

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

The Dental cosmos

THE
DENTAL COSMOS:
A
MONTHLY RECORD OF DENTAL SCIENCE.

Dedicated to the Interests of the Profession.

EDITED BY
EDWARD C. KIRK, D.D.S. Sc.D.

Observe — Compare — Reflect — Record.

VOLUME XLIX—1907.

PHILADELPHIA:
THE S. S. WHITE DENTAL MANUFACTURING CO.,
CHESTNUT STREET, CORNER OF TWELFTH.

1907.

CONTENTS OF VOLUME XLIX.

1907.

ORIGINAL COMMUNICATIONS.

Acid Auto-Intoxication and Systemic Disease the Cause of Erosion and Abrasion	1225	Experiments and Observations on the Wasting of Tooth Tissue Variousl Designated as Erosion, Abrasion, Chemical Abrasion, Denudation, etc.	1, 109, 225
Alveolar Infections: Extraction <i>vs.</i> Retention	708	Extensive Gold Inlays and Their Application to Bridge Work	690
Antiseptics and Disinfectants	579	Extraction (The) of Teeth a Surgical Procedure	354
Antiseptic Treatment of Pathological Conditions of the Oral Mucous Membrane	1132	F. D. I. Commission on Hygiene	366
Appendix to Article on "Facial Inharmonies"	930	Fifty Years of Dental Science with Its Fads and Foibles	1040
Banded (The) <i>vs.</i> the Bandless Crown	270	Forcing Eruption: a Case in Practice	266
Blue Light (The) and Heat as Therapeutic Agents	281	Free Dental Service in the Public Schools	565
Blue Ray (The) in Therapeutic Dentistry	824	Further Investigations of the Subject of Wasting	677
Burnished Gold Fillings	938	Gold Inlays	40
Case (A) of Congenital Total Absence of the Permanent Teeth	924	Gold Inlays in Compound Cavities of Molars. Involving the Mesio-occluding and Disto-occluding Surfaces	1034
Contour and Occlusion Obtained with Cast Fillings Without Waxing or Investing	468	Ground Porcelain Corners with Mechanical Anchorage	143
Corrected Case (A) of Pronounced Malocclusion of the Deciduous Teeth	820	Hygiene Maintained During the Progress of Orthodontia	943
Crowns Without Solder. Bridges With and Without Solder. and a Talk on Crown and Bridge Work	1251	Is the Cemented Filling the Filling of the Future?	1121
Degeneration (The) of Tissue. with Special Reference to the Oral Mucous Membrane	1025	Local Anesthesia in Dental Operations	555
Diagnosis (The) and Treatment of Antral Suppuration	909	Loss (The) of Teeth in Childhood, and Its Effect on Occlusion and the Face	1153
Dr. Miller's Observations on the Wasting of Tooth Tissue Variousl Designated as Erosion, etc., Viewed in Their Relation to the Power Possessed by Saliva of Controlling Acid Decalcification	801	Manual Training an Essential to Dental Education	469
Early Diagnosis (The) of Cancer	726	Method of Constructing Crowns for the Anterior Teeth	578
Educational Influence (The) of the So-called "Dental Meeting." Apart from Its Professional or Social Value	724	Method (A) of Repair that Can Successfully be Applied to Some Cases of Fractured Bridge or Crown Facings	280
		Method of Taking Impressions for Porcelain and Gold Inlays by Means of Strips of Aluminum in Combination with Dental Lac	454
		New Adaptation (A) of the Microscope to Dentistry	358

New and Accurate Method (A) of Making Gold Inlays.....	1117	Removable Bridges with Gold Inlay Abutments and Saddle and Vulcanite Attachment	154
New and Easy Method (A) of Making Perfect Gold Fillings.....	146	Repair of Porcelain Fillings.....	369
New Method (A) of Obtaining Plaster Impressions in Difficult Cases.....	278	Report of a Case of Extensive Injury to the Bones of the Face, and of a Case of Post-Typhoid Osteomyelitis of the Mandible.....	262
Nitrous Oxid and Oxygen: Its Possibilities and Practicability as a General Anesthetic	1140	Retention (The) of Deciduous Teeth in Adults	921
Non-union of Double Fracture of the Mandible Successfully Treated After a Lapse of Two Months.....	728	Review (A) of the Methods Employed for the Retention of Fillings.....	362
On Preparing Dental Papers.....	1148	Rise and Development of Intermaxillary Force	443
On the Pathology of Pericemental Inflammation	695	Setting Crowns and Bridges with Gutta-percha	453
Opsonism Applied to Pyorrhea.....	570	Some Abscesses of Dental Origin which Open Outside the Mouth.....	919
Oral Hygiene in Public Schools and Institutions: What are We Going to Do About It?.....	559	Study (A) of the Vascular Lesions of the Dental Pulp: Their Complications and Clinical Significance.....	124
Orthodontia and Orthopedia of the Face	1262	Supplementary Retaining Forces as Auxiliaries to the Labial Retaining Appliance	23
Orthodontia as a Prophylactic Measure.	337	Surgical Treatment of a Deformed Maxilla	929
Orthodontia: Opening the Bite in the Regulation of the Teeth: A Metal Flange for Improving the Anchorage of Appliances, Moving Teeth, and for Harmonizing the Occlusion.....	343	System (A) of Crowning and Bridging by the Aid of a New Crown.....	1245
Our Old Stand-bys.....	936	System of Utilizing Atmospheric Pressure for the Retention of Lower Plates	371
Pharmacopeial Revision	573	Teeth (The) in Relation to Ear and Throat Diseases	553
Pierre Fauchard	1233	Three Orthodontia Cases	148
Platinum Matrices and Pure Gold in Inlay Work	817	Time-Saving Attachment (A) for the Arch Bar	1260
Porcelain Rod (The) in Dentistry....	31	Traumatic Lesions Incident to Crowns and Bridges	1046
Present Status (The) of the Porcelain Inlay	433	Treatment and Filling of Root-canals..	1044
Preventive Medicine	1136	Treatment of Pyorrhea Alveolaris....	247
Prosthetic Nomenclature	456	Unique Method of Supplying a Missing Anterior Tooth	153
Pulp-Mummification	940	Use (The) of Compressed Air in the Office and Laboratory.....	722
Purposes (The) and Accomplishments of Modern Orthodontia	1128	Vacancy (A) in Dental Journalism...	466
Rambling Discourse (A) on Inlays....	827	Value (The) of Association.....	1030
Recreation for the Dentist.....	717	Wanted!—A Pathological Sense.....	815
Recreations for the Dentist, with Some Basic Requirements	1255		
Reflected Shadows Accompanying Porcelain Fillings	438		
Relation (The) of Diet to Interstitial Gingivitis	808		

Papers in Society Proceedings.

Aging of the Tissues with Special Reference to Given Forms of Dental Abnormality and Disease.....	745	America a Land of Unlimited Opportunities	78
		And They Say 'Comparisons are Odious'	1078

Appeal (An) to the Younger Men of the Profession	859	Dental Society of the State of New York	1050
Co-operation in Dentistry	730	National Dental Association.....	105
Correction (The) of a Misplaced Anterior Tooth by Means of Porcelain....	985	Northeastern Dental Association.....	835
Correction (The) of Facial Inharmonies	850	Pennsylvania State Dental Society...	1065
Dental Education	598	"Pressure Anesthesia" and the Removal of Living Pulp.....	505
Discussion (A) of the Merits and Demerits of the Gold Inlay.....	392	Prophylaxis a Factor in Dental Education	503
Does the Cemented Filling Preserve Tooth-Structure Better than the Filling Inserted Without Cement?.....	616	Remarkable History (The) of the Profession and the Splendid Character of the Men of the Past who Helped to Build It Up.....	495
Educational Problem (The).....	172	Report of Committee on Operative Dentistry (Union Meeting at Washington, D. C.).....	613
Lymphatic Stimulation in Dental Practice	305	Report of Committee on Oral Hygiene (National Dental Association).....	292
New Pharmacopeia (The).....	840	Report of Committee on Practice (New York State Dental Society).....	50
Opening the Doors of Dental Knowledge to the People	1270	Rubber-Dam Method of Abutment Preparation, Interchangeable Facings, and Cementation	484
Operative Dentistry	185	Silver Nitrate and Preventive Dentistry	1090
Oral Hygiene in the State Association.	313	Some Thoughts Concerning the Contact of the Teeth.....	373
Oral Surgery. [Summary.]	1286	Thoroughness in Dentistry.....	753
Orthodontia of Today from the Standpoint of the Orthodontist.....	986		
Phases of Art in Prosthesis.....	379		
President's Address—			
Connecticut State Dental Association	947		

CORRESPONDENCE.

Army and Navy Dental Legislation, 1266, 1303	Instance (An) of the Endowment of a Dental School	283
Dental Instruments Included in Surgical Equipment of Russian Warships....	Matrix (The) as an Aid in Cavity Preparation	720
Dentists, Stomatologists, and International Medical Congresses.....	Mixture of Gases in Oxyhydrogen Blow-pipe	283
Distal Cavities in Deciduous Second Molars	Pulp-Mummification	1160
Dr. Miller's Litmus Test.....	Question (The) of Priority Again—"The Matrix as an Aid in Cavity Preparation"	834
Formalin and Tricresol in Combination in the Treatment of Putrescent Pulp.	Salol in Tooth-Powders.....	471
158, 284	Substitute (A) for Pin Facings in Repairing Bridges	1161
Gold, or Gold and Platinum, Cemented Linings for Amalgam and Gold Fillings		
1157		

PROCEEDINGS OF SOCIETIES.

American Dental Club of Paris. 753. 985. 1090	District of Columbia Dental Society and the Maryland State Dental Association	582, 740

ORIGINAL COMMUNICATIONS.

EXPERIMENTS AND OBSERVATIONS ON THE WASTING OF
TOOTH TISSUE VARIOUSLY DESIGNATED AS EROSION,
ABRASION, CHEMICAL ABRASION,
DENUDATION, ETC.

By W. D. MILLER, D.D.S., M.D., Ph.D., Sc.D., Berlin, Ger.

(I.)

SOME confusion has been occasioned by reason of the fact that various authors on the subject specified under the above title have given the affection different names according to their own conception of its nature, the result being to a certain extent the same as in the case of pyorrhea alveolaris, viz, that we have a multiplicity of names no one of which is fitted to all of the conditions and phenomena present.

In particular, the use of the word "erosion" (Lat. *e* + *rodere*, to wear off, to eat away, to consume, to corrode) has given rise to considerable confusion. It has been employed by many to designate a wearing away by mechanical means only, and undoubtedly this meaning is inherent in the word; in fact, we

get the term "rodent" (gnawer) from the same root. More commonly, however, and especially in pathology, we understand by erosion a superficial loss of substance caused by the solvent or corroding action of some fluid—as, for instance, the hemorrhagic erosion of the mucous membrane of the stomach; and in this sense it is always employed to designate an *acquired* lesion, whereas in dentistry the French and many other continental writers employ it—improperly, it seems to me—to designate an *hereditary* condition of the teeth for which Zsigmondy has recommended the very appropriate term hypoplasia (Gk. *hypo*, under, and *plassein*, to build), i.e. faulty development.

I am not an advocate of making new

names, nor do I believe that it is good policy to "swap horses while crossing the stream." I have therefore heretofore adhered to the old nomenclature. Recently, however, I have been repeatedly admonished of the fact that especially European readers are likely to be misled by the use of the term erosion. Accordingly, in order to guard against any misunderstanding, I give the following definitions of the terms to be used in this communication:

Wasting (wasting away, wearing away) is used in a collective sense to designate any kind of slow and gradual loss of tooth-substance characterized by a smooth, polished surface, without reference to the cause of such loss.

Erosion (*e + rodere*, to eat away) refers to the superficial chemical disintegration of tooth-substance.

Abrasion (*ab + radere*, to rub off) is a slow and gradual wasting away of tooth tissue by friction.

Attrition (*atterere*, to rub upon or against, to wear away by rubbing together) designates the particular condition in which abrasion is produced by the rubbing of teeth upon each other in mastication, etc.

Denudation is used in the ordinary sense of laying bare or divesting of a protecting covering.

Wedge-shaped defect is equivalent to the "keilförmiger Defekt" of German authors: a wasting away of the tooth at the neck, very often taking a form as though produced by a three-cornered file.

Hypoplasia (Gk. *hypo*, under, + *plasia*, to build)—faulty development—indicates the hereditary condition of the teeth which English and American authors have described by the terms pitted, grooved, honeycombed, atrophied, etc., and French and many other continental authors by the term "erosion."

Wasting produced by mechanical agents is equivalent to "abrasion;" by chemical agents, to "erosion;" by mechanical and chemical agents combined, to "chemico-abrasion."

There is scarcely a question in dental

pathology which has so stubbornly resisted all attempts at a satisfactory conclusive solution as that of the wasting of the teeth, and it is therefore not surprising that a great many different theories have been promulgated regarding it.

It would be beyond the limits set for this paper if we were to attempt to analyze all those theories; besides, it will suffice for our present purpose simply to call attention to them. At the same time I will beg those who are interested in this question to consult my communication printed in this journal for March 1904, of which this may be considered a continuation.

Among the various causes that have been put forward to account for the wasting of the teeth, the following may be mentioned:

(1) Mechanical agents, in particular the tooth-brush (John Tomes, Zsigmondy Sr., Zsigmondy Jr., Salter, Niemeyer, Billeter, Zinkler, Von Metnitz, Parreidt, etc.). Parreidt believes, however, that the brush does not act upon the teeth unless they are in some way predisposed.

(2) Mechanical agents in the presence of alkalies or acids. (Jul. Scheff.)

(3) Resorption. (Linderer.)

(4) Chronic caries. (Leber and Rotenstein.)

(5) Friction of folds of the mucous membrane. (Wedl.)

(6) Exfoliation. (Baume.)

(7) Alkalies. (Baume.)

(8) Acids. (Frey, Darby, Snyder.)

(9) Acid secretion of the mucous membrane. (Hagelberg, Coleman, Truman, Kirk, Burchard, and others.)

(10) Acids in combination with mechanical agents. (Schlenker, Walkhoff, M. Bastyr.)

(11) Agents which attack the organic matter of the tooth. (Znamensky, Michaels, Preiswerk, A. Bastyr.)

(12) Electrolytic action. (Bridgman, Garretson.)

(13) Defective development. (Bland-Sutton.)

This list makes no pretense to being complete. Any student of the question

can easily add names under the different headings.

The most recent and detailed communication on the subject of erosion is by Alfred Bastyr: "Der erworbene Defekt der harten Zahnschubstanzen," in Scheff's "Handbuch der Zahnheilkunde," vol. ii, part 1. From this communication I have taken many of the above data referring to the literature of the subject.

Bastyr comes to the conclusion that *acids, or in general agents which dissolve the calcium salts of the teeth, can never produce wedge-shaped defects*. In all such cases only decay at the neck of the tooth is the result. This is a confirmation of a point brought out by me in this journal for March 1904, though we shall see that there are many modifying influences and conditions to be taken into consideration. Bastyr is of the opinion that in the majority of cases of wedge-shaped defects some substance acting in connection with mechanical agents dissolves or diminishes the organic matter of the tooth. But what this substance is, Bastyr is not able to say, inasmuch as he did not succeed in extracting the organic matter of the tooth by chemical processes.

In my studies on the wasting of the teeth I have found it convenient to concentrate my attention upon the following points:

- (1) The action of mechanical agents in the production of wasting.
- (2) The action of substances which attack the inorganic constituents of the teeth (acids or acid salts).
- (3) The action of (1) and (2) combined.
- (4) The action of substances which attack the organic matter of the tooth.
- (5) The action of (1) and (4) combined.
- (6) The action of (2) and (4) alternating.
- (7) The action of bacterial ferments.
- (8) The action of electric currents in the mouth.

Furthermore, the question of the relation of gout and rheumatism to, and the causal connection of potassium sul-

focyanid with, wasting of the teeth have received especial attention.

I. ACTION OF MECHANICAL AGENTS IN THE PRODUCTION OF WASTING.

There has not been for years any doubt in my mind that most cases of wasting observed in our practices are due to mechanical action—which means in particular the action of the tooth-brush combined with tooth-powder.

This conviction has been confirmed by observations made during the last few months. Let me refer to a few of these cases in order to substantiate the view just expressed, or to furnish my readers with the opportunity of checking me if the above conviction appears to them not to be well founded.

Case 1 (for which I am indebted to Dr. Griswold of Hamburg). Male, age fifty: in good health except for a tendency to gout after too much wine. Teeth strong and yellowish. Saliva alkaline, mucus at one time alkaline, at another slightly acid. *The incisors, which are prominent, show no wear at all, whereas the canines and bicuspid's above and below are completely worn away as shown in Fig. 1. The upper left canine was devitalized and filled in November 1901: gutta-percha, cement, and gold succeeding each other.*

The wearing away, which began at the cusp, had involved the whole of the labial surface and exposed the root-canal in December 1905, the dentin, gutta-percha, cement, and gold presenting a continuous smooth surface. The lower first bicuspid was crowned with gold in February 1904. In December 1905 the crown was completely worn through on the buccal surface. The patient demonstrated his method of brushing to Dr. Griswold, confirming the suspicion that he brushed only the sides of his denture, the short upper lip and projecting incisors preventing his getting the brush between the incisors and the lip.

The patient employed a much-used English tooth-paste for over twenty years. It contains a surprising amount of a gritty substance, the hasty washing of one box of the paste yielding over two thimblefuls of grit which seems to consist chiefly of pumice. A microphotograph of this grit is shown in Fig. 2.

Case 2. Male, age sixty-five, of rheumatic diathesis. Saliva abundant, thin, without foam, moderately cloudy, little sediment; re-

action slightly alkaline; reaction of mucus slightly under normal. sulfocyanids slightly amphoteric. Nessler's reagent gave abundant above normal, phosphates abundant, chiefly

FIG. 1.

Severe wasting of canines and bicuspid produced by the employment (for over twenty years) of a much-used English tooth-paste. (Incisors free from abrasion.) At 7, abrasion of gold crown by action of tooth-brush and paste.

FIG. 2.

Photomicrograph of sediment obtained by washing tooth-paste referred to under Fig. 1.

precipitate (which by the way, does not necessarily indicate ammonia). Chlorids soluble phosphates of sodium and potassium. The front teeth, and to a less extent

the bicuspid, were almost completely denuded of their enamel. In the lower jaw the destruction was not quite so extensive, being more pronounced at the necks.

This man also used the same preparation for about twenty years. He was inclined to the view, however, that the paste was not the cause of the wasting, since his wife, he said, also used it without any bad result to the teeth. On closer inquiry it turned out that his wife had used the paste only half as long as he had. On a subsequent occasion the opportunity was given me of examining the teeth of his wife, when I found that she also had pronounced wasting, beginning at the necks of the teeth and extending more or less upon the enamel. Three of the defects had already been filled with gold.

Case 3. Physician, age forty-seven; arthritis of the knee joint. No gout so far as he is aware. The saliva was not examined. The front teeth were badly wasted on the labial surface. The patient dates the beginning of the trouble from the time he commenced using an English tooth-paste which consists of prepared chalk along with a small amount of pumice. He enjoys looking at his beautifully white teeth and brushes them excessively, so that his wife frequently laughs at him on account of the time spent over them.

Case 4. Woman, age forty-five, in perfect health; denies all suspicion of gout, rheumatism, or any other malady. Saliva normal in quantity and character. The upper centrals are worn away from the cutting edge, and these edges slope up toward the distal margin, permitting the brush to strike with full force against the mesial angle of the lateral, which is accordingly worn away on both teeth. Other teeth above and below are also extensively wasted. A gold filling at the neck of the first bicuspid is badly worn, and a gold crown on the second bicuspid shows distinct wearing of the gold band at the margin of the porcelain. *Gold crowns on M 1, both above and below on left side, are worn through on the buccal surface.* Her tooth-powder has an exceedingly gritty feeling when held between the fingers, and contains a large percentage of pumice and another undetermined insoluble grit, and *her tooth-brush wears down rapidly.*

Case 5. Woman, age forty-eight; rheumatic, and in moderate degree diabetic. Salivary secretion abnormally slight, saliva foamy, liquid, alkaline. Mucus of lower lip alkaline, of upper lip amphoteric. Up to two years ago she used a sharp tooth-powder.

but then changed to one without grit, and began brushing vertically. She claims that the wearing has made no progress since the change was made, which is apparently the case, as the surfaces are in no case highly polished, but rather dull, and partly discolored by a thin deposit.

Case 6. Male, age forty-five; healthy, with no pronounced diathesis. Strong teeth. Saliva normal in quantity, moderately slimy, alkaline; mucus alkaline to neutral; ammonia above normal, chlorids normal, sulfo-cyanids under normal, phosphates in moderate quantities. She had used for a number of years the English tooth-paste referred to in Cases 1 and 2. Since leaving it off the erosion has made but little or no progress.

Case 7. Male, age fifty; affirms that he has no complaint whatever, in particular neither gout nor rheumatism. Reaction of saliva alkaline; mucus of upper lip slightly acid, of lower lip neutral. Extensive wasting, especially on the *right* side. He holds the tooth-brush in the left hand, and has for over thirty years employed the tooth-paste just mentioned.

These are only a few of the cases which I have examined, and which have shown the predominating influence of brush and powder. Even many cases which have been cited to me as evidence against the mechanical origin of wasting seem to admit of a ready interpretation in accordance with it. A tooth was sent me by Dr. Brunsmann of Oldenburg, a lower lateral incisor which had been loose for many years, showing wearing of the lingual surface at the neck, due to the rubbing of a plate, and also a slight wearing of the labial surface at the neck. The neighboring teeth are firm and free from wear. Dr. Brunsmann argues that the condition in this case cannot have been produced by the brush, since the neighboring teeth must likewise have been affected. The fact, however, that this tooth had been loose for many years, justifies the inference that the neck had lost the protection afforded by the gums; in other words, it was denuded and therefore subjected to the direct friction of the brush. Dr. Brunsmann likewise reported to me a case in which an upper second bicuspid alone had a wedge-

shaped defect at the neck. Here, again, the tooth stood alone, its neighbors having been lost, and it was tilted inward so far as to cause an exposure of the dentin at the neck.

Many cases have been referred to of teeth showing wasting on the lingual surface, but these are exceedingly rare; by far the majority of cases of so-called erosion found in collections of teeth have been produced by friction of plates,

FIG. 3.

a, Wasting of lingual surface; *b*, of amalgam filling, produced by plate.

clasps, antagonists, etc., as a careful examination with the magnifying glass will show. We usually find the surface of such defects studded by many oval or longish facets, giving sometimes the appearance as though a miniature rodent had been gnawing at the tooth. Where these defects have been filled, the filling may show the same appearance. (Fig. 3.)

It must also not be forgotten that the lingual surface of the teeth is quite accessible to the brush, and, especially in the upper molars and bicuspsids, may be reached about as easily as the buccal sur-

face. This is well illustrated by the following case:

The patient, a lady in the fifties, has worn a full upper plate for many years. Of the lower teeth only the incisors, canines, and three bicuspsids are left, and the teeth are all strongly protruding. (See Fig. 4.) The left incisors, *B, C*, both show wearing away at the neck, slightly sloping up toward the right side. The left canine, *A*, is very much rounded off distally. *The right incisors, D, E, have amalgam fillings on the lingual surface, and those are markedly worn, the enamel margins standing high above the amalgam and the marks of the brush being plainly visible.* Wasting is also present in the labial surface. The absence of teeth in the upper jaw and the protrusion of the lower teeth made it just as easy for the patient to brush the lingual as the labial surfaces, and having only the lower front teeth to look after, she did it well, using besides a sharp tooth-powder containing an insoluble grit.

Then, again, extraordinary factors may occasionally come into play to produce wasting in unexpected places. For example, Professor Warnekros of Berlin related a case to me in which a man had for a long series of years been in the habit of taking lozenges into the mouth and rubbing them with the tip of the tongue against the lingual surface of the lower incisors, by which means he had in the course of many years produced distinct grooves in them.

Reports of wasting in the teeth of animals, which have appeared from time to time in the journals, have little bearing on the question. A carnivorous animal may readily wear a groove in his canines at the neck, where the enamel is thin; and likewise herbivorous animals—particularly ruminants that graze on short grass on sandy soil—may wear the teeth away at the necks by throwing the bolus of food about for hours daily. Much has been made of the fact that the teeth of seals show defects resembling wasting, but if it be true, as stated by Coleman, that seals take stones and probably also sand into their mouths, the fact is easily accounted for. I intend making the wasting of the teeth of animals the subject of a separate communication, and shall therefore not

enter into a detailed discussion of this question here.

ARTIFICIAL PRODUCTION OF WASTING BY MECHANICAL MEANS (ABRASION).

Not only do we meet with many cases of extensive abrasion of the teeth where gritty tooth-powders or pastes have been used, but it is a very easy matter to produce artificial abrasion by use of such

or of the brush alone was to be tested, the teeth were fixed in sealing-wax, as it was found that plaster of Paris itself contains a sufficient amount of grit to act upon the dentin. A piece of pink gutta-percha was also placed across the root to represent the gums, as this material very stubbornly resists the action of the brush. With some of the much-extolled preparations on the market it is quite easy, by applying the brush as nearly as possible

FIG. 4.

Wasting of lingual surface; wearing down of amalgam filling in D and E, produced by brushing with tooth-powder.

preparations. In Fig. 5 we have silhouettes of sections of teeth showing the effect of different powders applied for two hours by a moderately stiff brush.

The tooth to be experimented upon was fixed horizontally in plaster of Paris, and when a single tooth was brushed, a piece of pink gutta-percha was placed at each side to represent the neighboring teeth and prevent the brush from acting too much on the sides of the tooth. When the action of very fine substances

in the same manner as it would be used in the mouth, to cut the tooth half through, exposing the pulp, inside of two hours. (See Fig. 5.)

Besides the substances whose action is shown in Fig. 5, a great many other tooth-powders were examined. In fact, I was not satisfied with examining the preparations microscopically, but where there was any doubt I tested them by brushing the teeth with them. Of the dentifrices examined a considerable num-

ber cut the teeth rapidly; while nearly all the others cut the teeth to some extent—least of all that I have examined, one which consists almost wholly of sodium bicarbonate. I was surprised to find that even precipitated chalk wore the dentin away rather rapidly—but this one can understand in view of the fact that the substance consists of a mass of fine crystals, which although they are very small, are still sharp, and sufficiently hard to abrade the dentin. (See Fig. 6.) Prepared chalk acts upon the teeth with a rapidity depending upon the amount of impurities which it contains. We shall find on washing out prepared chalk that among different preparations some contain considerable quantities of remains of shells and other gritty substances, which make them unfit for use as tooth-powder. Other preparations which are comparatively free from these impurities act more slowly upon the dentin. Powdered tartar wore away a very shallow notch in a tooth in the space of four hours; soap produced a slight but clearly visible effect; saliva, as well as water, barely more than polished the surface. Still, on brushing three teeth, set in sealing-wax, continuously for six hours with a new, moderately stiff brush, the margins of the scratches caused by the forceps in extracting were smoothed off, so that a certain slight effect may, after all, be produced.

In the accompanying illustrations photomicrographs of some of the chief constituents of mercantile tooth-powders or the powders themselves are shown under a moderate magnification: Fig. 7, pulverized pumice; Fig. 8, an insoluble grit possibly powdered oyster-shell; Fig. 9, a powder widely advertised in America; Fig. 10, a powder used for a long series of years—as long as he could remember—by an old gentleman, who had completely divested his teeth of their enamel.

The form of the cavity produced depends upon the shape and size of the brush, as well as upon the position and thickness of the gutta-percha strip representing the gums. This strip forms a kind of a directing line to the action of

the bristles; they are pressed together at this line, and consequently cut deepest there. When the teeth are brushed without any such boundary we get a cavity of a different shape. (See Fig. 5.) The relative position of the teeth to each other when a whole row is brushed at the same time, also markedly influences the result. Very often several grooves and notches appear, such as are occasionally met with in the mouth.

The action of the brush and powder upon the enamel is slower than upon the dentin, so much so that some have stated that it is not possible to wear away the enamel by such means.

In an article in the *Dominion Dental Journal* for September 1906, taken from the *Dental Brief*, the name of the author of which is not given, we have the computation based on results obtained by experimenting with a brush wheel, with which Methuselah might have brushed his enamel with pumice twice or even four times a day for his whole life (969 years) without producing anything more than a brilliant polish. Supposing a man brushes his teeth ten seconds four times a day, we shall find on computing that in the course of 969 years he would have brushed altogether 483 days at eight hours a day. I can assure the gentleman that he would be spared the trouble, as he would have no vestige of a tooth left, either dentin or enamel, by the time he had well begun his task.

With a brush wheel two inches in diameter, revolving with moderate rapidity, I wore away the greater part of the enamel of the central incisors in an upper denture in ten hours. Wedge-shaped defects were produced, extending through to the pulp-chamber, and on the left central the loss of substance extended along the mesial approximal margin two-thirds of the distance to the cutting edge of the tooth. I did not attach any importance to this result, as the conditions of the experiment differed too much from those actually present in the mouth. More trustworthy results were obtained by use of a tooth-brush mounted horizontally, and run by a motor at a rate of 240–460 os-

cillations per minute, which arrangement is referred to when I speak of the motor brush. In most of my experiments, however, I adopted the more natural and more reliable method of brushing with the hand—at an immense sacrifice of time, it is true, but still I think that the sacrifice was warranted by the importance of the subject. My assistant and I have spent during the last year an average of sixteen hours a day, and altogether, on a very moderate estimate, 10,000 hours on the work here recorded.

Fig. 12 we have a photographic reproduction showing the effect of brushing with a much-used English tooth-paste and powdered oyster-shell alternately, for 8, 11, and 18 hours respectively. (See also the table on page 18.)

From these experiments it follows that the enamel is certainly susceptible to the action of gritty tooth-powders, and that within a reasonable length of time.

We may put it down as an axiom that anyone who brushes his teeth once daily *thoroughly*, using a gritty tooth-powder.

Fig. 11.

Abrasion of teeth produced by brushing with a much-used English tooth-paste for eighteen hours. (Remains of gold filling in first bicuspid.)

As for the question at present under consideration, I found that on brushing the left side of a lower denture with a much-used English tooth-paste, the whole of the enamel and the dentin of the buccal surface of the canine and bicuspid were brushed away, exposing the pulp-chamber in eighteen hours. The molars were deeply notched. (Fig. 11.) This would correspond to brushing each half of the dental arch, above and below, for ten seconds daily for eighteen years. Some brush considerably more and some considerably less than this. In this experiment enamel, dentin, and gold wore away with about equal rapidity—a noteworthy result, to which I refer later on. In

will invariably wear away his teeth at the necks inside of a very few years, *unless they are protected by healthy gums.* The wearing away will gradually extend upon the enamel, and in the course of ten to twenty years considerable portions of the enamel plate may be destroyed. It is to be noted in this connection that the enamel, while being worn away, may preserve a high polish, and it may even escape the notice of the dental practitioner that the plate of enamel is gradually becoming thinner. I have had dentists say —“I have been using a gritty tooth-powder for ten or twenty years, and I have no wasting;” yet a careful examination with a magnifying glass has shown

the worn surface readily recognizable by anyone who has made a study of this subject, and looking at the tooth from the cutting edge we may find the plate of enamel as thin as paper. As a matter of fact we seldom notice that the enamel is wearing away until the whole plate is broken through and the dentin exposed.

brush them. One patient, suffering from abrasion, told me that he often spent as much as five minutes over his teeth; and one lady assured me that she devoted one hour daily to the care of her teeth—a rather strong exaggeration, no doubt. Others perform the whole operation inside of fifteen seconds. Some charge the

FIG. 12.

Effect of brushing with a much-used English tooth-paste and powdered oyster-shell: *A*, at beginning; *B*, after eight hours; *C*, after eleven hours; *D*, after eighteen hours.

A case recently came to my notice in which a young lady, who is very proud of her white teeth, had, by a vigorous use of Chinese tooth-powder consisting chiefly of pumice, very perceptibly worn down the enamel of her front teeth, inside of three years.

It must also be borne in mind that there is a vast difference in the manner in which different people brush their teeth. In fact, there are about as many ways of brushing the teeth as there are people to

brush with a great quantity of powder, others only dip the tip end into it, others again use powder only occasionally, and many not at all. Some run the brush horizontally along the necks of the teeth, some diagonally from the cutting edge of the incisors across to the neck of the first molar. The manner of holding the brush and the shape of the teeth are also factors of importance; likewise the inclination of the teeth to each other and to the alveolar process—as has been pointed

out by S. P. Mummery. The only pronounced case of wasting of enamel I have met with in an experience of twenty-two years in a dental clinic was that of a man who closed his teeth when he brushed them. The upper row closed over the lower, and formed a channel along which he worked the brush backward and forward, and in the course of years he wore away a great part of the enamel of the lateral incisor, canine, and bicuspid of the left side of the lower jaw, using cigar ashes and powdered oyster-shell as a tooth-powder.

Almost invariably the wasting will be found to attack the prominent teeth in the arch most severely, and will not be found on those teeth which are not reached by the brush. This fact is, however, modified to some extent by the shape of the teeth, as indicated above. If the labial surface of an incisor be markedly convex, we shall find in passing a brush over the surface horizontally that the bristles divide in the middle, and spread out toward the neck and the cutting edge of the tooth. The result *may* be that we shall get wearing at the neck and at the cutting edge, while the more prominent point of the tooth remains comparatively free. So, too, if a tooth be so set as to make an angle with the alveolar process, we shall find a tendency of the bristles to work up toward the margin of the gums, with a corresponding effect at this point; but wherever a tooth is, for instance, rotated on its axis, so as to make one margin stand higher than the other, this margin will be more severely attacked, in fact it will often be the only margin affected. The same is also true of experimental wasting. It is sometimes said that teeth which stand inside of the arch are subject to wasting, and so they are. If we fix three teeth in plaster of Paris—the middle one considerably lower than the other two—and brush them, we shall find the middle tooth becoming worn as well as the others, but not to the same extent, and that too is the case in natural wasting. We never find a tooth which lies lower than its neighbors as strongly cut as they,

unless it be a case in which there has been a change in the position of the teeth; but such a case has never come to my notice.

A sufficiently vigorous use even of prepared chalk will tell upon the teeth in the course of time. In a case of severe wasting which had been gradually progressing for thirty years, nothing more gritty than *creta preparata* could be made accountable. The patient used this three times a day, and so vigorously that she wore away *two brushes every month*. No wonder that the teeth also suffered. The *condition of the tooth-brush*, by the way, may sometimes give us a clue to the cause of the evil, and when we find the bristles wearing down rapidly we may be pretty sure that there is a gritty powder, and vigorous usage back of it, and that the teeth are wearing also. Anything which wears away the brush will also wear away the teeth, particularly the dentin. A brush that has been used with powder so as to cut a tooth through to the pulp-canal, as in Fig. 5, will show but slight wear, and in brushing away the entire enamel and a good part of the dentin from the facial surface of five teeth, only two brushes were required. In these the bristles were worn to within one-quarter inch of the ivory.

My attention was recently called to a tooth-brush which had been in use for twelve years. No powder had been used with it, and still it was stated that the bristles were worn down to within one-quarter of an inch of the ivory. This hardly seems a fair test, since the boiling to which the brush had been subjected as a means of disinfection must have materially affected the durability of the bristles. During the ordinary life of a tooth-brush—six months to a year—we will find no shortening of the bristles by wear except a powder be used—unless they are rendered brittle by some process of disinfection. A tooth-brush used *without powder* continuously for six hours in brushing three teeth set in sealing-wax did not show a trace of wear.

I have made it a point to ask for the brushes of patients suffering from wast-

ing of the teeth, and have a collection which is very instructive. We must, however, guard against a bit of deceit which is sometimes practiced by patients whose brushes are not in good condition, and who send in a new brush instead of the old one which we asked for.

Taking it all in all, I have come to the conclusion that we have formulated our question regarding wasting of the teeth wrongly. It should not be, Why do some people have it? but, Why do not many more people—in fact why does not everyone who uses a brush and powder—suffer from it? Here the answer is comparatively easy to give. So long as the necks of the teeth are covered by healthy gums, they are effectually protected against the action of the brush, and it takes a number of years to wear away the enamel sufficiently to expose the dentin; before this time, the wear, although it may be in progress, escapes our notice. Then again, as already pointed out, it is only a small minority of our patients who really give their teeth a thorough brushing, even among those who claim to be particularly scrupulous in this respect; and an occasional brushing only, with a little powder for a few seconds, will be a long time in producing any appreciable effect.

SUSCEPTIBILITY OF DIFFERENT GRADES OF TEETH TO ABRASION.

A general impression seems to exist that wasting is a lesion affecting chiefly teeth of good structure, well-developed, yellow, so-called hard teeth. My observations have not always tended to support this impression. I think we may say that, in general, teeth badly affected are of the yellow grade, though I have noted very many exceptions. It appears to me, moreover, that the chief reason for the impression that wasting is characteristic of yellow, hard teeth is to be found in the fact that this lesion is observed chiefly in advanced age, and that the color of the teeth likewise becomes darker as age advances. Nevertheless, I have

given attention to the question as to whether teeth of different color are susceptible in different degrees to mechanical action, and have made many experiments relative to it. The teeth were fixed in a row, the light and dark shades alternating, and subjected in some cases to the action of the motor brush, in others to the hand brush.

Eight teeth were fixed at equal distances from each other in plaster of Paris, and as nearly as possible on the same level, 1, 3, 5, 7 being teeth of lighter color, 2, 4, 6, 8, more yellowish. They were then brushed with the motor brush and pumice until about half brushed away. On laying a strip of articulating paper upon the surfaces, and pressing it down with a perfectly straight edge, the markings on 1 and 7 indicated that their surfaces lay a trifle higher than those of the other teeth. 5 and 6 lay sufficiently low to be untouched by the paper; in other words, they had been brushed away somewhat more than the other teeth, though the difference was slight. But as one of these was a hard, and the other a soft tooth, this result could not be taken as indicating whether one class is more susceptible to the action of the brush than the other.

In a second experiment, a senile tooth with a transparent, amber-like root was distinctly less affected than the neighboring white teeth.

In a third experiment, in which the teeth were brushed with pumice wet in a five per cent. solution of oxalic acid, slight differences could be detected, but not sufficient to justify a definite conclusion.

In a further experiment, in which six teeth, white and yellow alternating, were ground down to the middle before the experiment was begun, one very whitish, badly developed tooth showed considerable more wear than the other five, which were about equally affected.

We may accordingly say at present, that while there seems to be a slight difference in the resistance which the dentin of different teeth offers to the action of the brush and powder, further experi-

ments will be necessary before we can come to a final conclusion regarding this point.

With regard to the enamel, there is no doubt that its structure has great influence upon its susceptibility to mechanical action. I have seen badly developed, chalky spots in the enamel wear away much more rapidly than the surrounding normal tissue. Also, in the case of a hypoplastic tooth, I found, on splitting it into halves and brushing the split surfaces with pumice, that the enamel wore away faster than the dentin, whereas, as a rule, dentin wears away approximately fifteen to twenty times as fast as does enamel.

In an experiment in which five teeth were brushed three hours with chalk, eight hours with a proprietary tooth-powder, four hours with twenty per cent. pumice, and three hours with pure pumice, the enamel of a bicuspid was completely gone at the eighteenth hour, while that of a whitish incisor did not yet show a break. In another case a brushing of thirty-three hours with an English tooth-paste and fourteen hours with Chinese tooth-powder was required to accomplish a result similar to that shown in Fig. 11, and produced in eighteen hours.

The enamel offers the greatest resistance to friction with powders when it is applied to the free surface and to the *ends* of the prisms. In case of wedge-shaped defects, either natural or experimental, which encroach upon the enamel in a plane nearly parallel with the direction of the prisms, and in which the friction is consequently applied to the *sides* of the prisms, we find the enamel yielding about as rapidly as the dentin.

WEARING AWAY OF FILLINGS.

A potent argument in favor of the mechanical origin of wasting is to be found in the fact that fillings of amalgam and gold so often suffer from it. In fact, where cavities produced by the process under study have been filled for some years with either of these materials, we

shall invariably find considerable wearing away of the filling unless the patient has changed the manner of caring for his teeth. The wearing of the filling may often escape the notice of the patient as well as that of the dentist, because the tooth-substance wears down at the same time. I have repeatedly seen gold fillings

FIG. 13.

Wearing out of amalgam filling.

polished, cupped, or grooved by the action of the brush, and amalgam fillings almost worn out altogether, as was the case in the tooth seen in section in Fig. 13.

In Fig. 14 I have reproduced a case which is particularly deserving of attention:

The patient, a man of about forty-five years, was in fair health with the exception of an occasional attack of asthma and a rheumatic tendency. The loss of substance was most extensive in the front of the mouth, growing gradually less toward the back, the third molars being quite free; the facial surface of the six front teeth, in particular, as well as the cutting edge or cusp, was completely denuded of enamel, and also a fair amount of dentin had been lost, the two surfaces meeting in a sharp edge at right angles. On closing the mouth there was a space of about one-fifth of an inch wide between the upper and lower rows. The teeth were exceedingly sensitive to the excavator, as well as to changes of temperature and to fruit juices.

In the year 1880 the surfaces of all the teeth were restored with gold, which was well hammered and built down (or up) almost enough to restore the articulation. In the course of ten years the gold had for the most part completely worn away from both the facial surface and the cutting edge, although

at the last the teeth did not come together to within one-fifth of an inch, in a number of them only the gold in the retaining points and grooves being left. In some of the teeth the gold, dentin, and enamel were all wearing away at the same rate, neither of these substances projecting above the others. Whatever the cause of the wear in this case, it affected all three substances about equally—on the cutting edge absolutely equally, as was also the case in the experiments shown in Fig. 11.

amalgam, another with gold, and were brushed for half an hour with a motor brush and 10 per cent. pumice. The dentin wore away rapidly at the neck; the amalgam filling likewise showed a considerable wearing, and four parallel grooves formed on its surface; the gold was but slightly affected, and the enamel least of all.

When a tooth containing a *small* fill-

FIG. 14.

Case of gradual wasting of both tooth-substance and filling material notwithstanding the open bite.

COMPARATIVE WEARING OF FILLINGS AND TOOTH-SUBSTANCE.

The rate of wearing away of fillings and tooth tissues is a matter of great importance, as it very often gives us a clue to the nature of the process, which would otherwise have remained in doubt. For that reason a large number of experiments were made relative to this question. If, for example, we brush a block of ivory containing a gold filling in the center with 5 to 10 per cent. pumice, we find the ivory wearing away and the gold standing out above the surface. Four teeth were fixed in plaster of Paris, one of them filled on the exposed surface with

ing of gold or amalgam on the free surface of the enamel is brushed, the cement and the dentin wear away most rapidly, then the amalgam, after that the gold, and last of all the enamel. The gold, although considerably softer than dentin, is not so brittle, and wears less rapidly, consequently we shall usually find the surface of the gold standing higher than that of the dentin, and slightly lower than that of the enamel. When *large* gold fillings are inserted—covering, for example, a greater part of the labial or buccal surface—then, under the action of the brush and powder, enamel and gold wear down about equally. Also when the brush strikes the enamel parallel to the

direction of the prisms, the enamel wears approximately with the same rapidity as the gold. For instance, if we grind down a molar tooth about one-third of its diameter and insert fillings of gold, pink gutta-percha, and amalgam, and then after the setting of the amalgam brush the surface with a powder, we find that the dentin becomes cupped out sometimes in a striking fashion, leaving the margin of the enamel standing above the surface.

shown in Fig. 14. In the case of badly developed enamel it may wear away even faster than the dentin, as I found particularly in a tooth with faulty (hypoplastic) enamel.

In examining a severe case of wasting of the lower front teeth (in the practice of Zahnarzt Brausewaldt), I was struck by the marked wearing of an amalgam filling on the labial surface of the left central incisor, and the question came up,

A. Gold filling in left canine.

	1 h.	3 hrs.	5 hrs.	7 hrs.	9 hrs.	11 hrs.	13 hrs.	16 hrs.
(a)	.00	0.06	0.10	0.13	0.19	0.30	0.38	0.56

(c)	0.10	0.20	0.30	0.42	0.50	0.60	0.65	0.90

D. Right central from which the enamel had been removed.

(a)	0.35	0.90	1.40	1.86	1.94	2.60	3.00	3.30
(b)	0.20	0.45	0.90	1.38	1.68	2.10	2.45	2.70
(c)	0.10	0.24	0.24	0.60	1.05	1.60	1.80	2.10

The enamel, however, also wears down, and we shall find it, the gold, and the pink gutta-percha standing at very near the same level, the amalgam being somewhat lower.

Occasionally I have observed, without being able to account for it, that gold, enamel, and dentin have worn down with equal rapidity, so as to produce a perfectly flat surface. In the case of the artificial wasting shown in Fig. 11, the first bicuspid had a large gold filling on the buccal surface; it is all worn away except the bit seen at A in the photograph, and the enamel, dentin, and gold form a perfectly flat surface. We found the same condition in the case of natural wasting

How much wear on the enamel and dentin does that correspond to, or how much of the wasting observed has taken place since the insertion of the filling referred to? In the attempt to answer this question, and to determine in general the relative rapidity of wearing of tooth-substance and filling, the following course was adopted: In a lower jaw the left canine was furnished with a large gold filling on the labial surface, the central similarly filled with amalgam, the right first bicuspid with gutta-percha, and the second bicuspid with a small gold filling at the neck. The left lateral stood slightly outside of the arch, and the right lateral inside. The enamel was re-

moved from the right central on the lower half, i.e. from about the middle of the crown to the neck of the tooth. The teeth were now brushed for sixteen hours with a much-used English tooth-paste alternating with powdered oyster-shell, and the depths of the teeth were carefully taken every two hours with a nonius.

The measurements were taken from three different points: *a*, at the neck of the tooth; *b*, at the middle of the crown; *c*, near the cusp or cutting edge. The table opposite shows the wear in millimeters.

It will be seen that the gold filling wore least of all, and more at the neck and tip than in the middle of the crown. The lateral incisor naturally suffered most at the neck (*a*), where the enamel was wanting. At (*b*) the wear proceeded slowly for the first seven hours until the enamel was broken through, when it went on much more rapidly. At (*c*) the same stage was not reached until near the close of the experiment—13th hour, the enamel being thicker toward the cutting edge. Note the comparatively rapid wearing of the amalgam filling in the left central. The slighter wear near the cutting edge (*c*), is due to the fact that the filling was here protected by strong enamel walls and the whole tooth stood slightly inside the arch. The most extensive wearing is seen in the right central, where the action was upon the dentin. The small gold filling in the neck of the second bicuspid stands out like the head of a pin. Likewise the pink gutta-percha is considerably higher than the surrounding dentin.

From this and various other experiments I have determined that gold wears according to the circumstances noted above, as rapidly or slightly more rapidly than normal enamel. Amalgam wears about four times as rapidly as gold, and dentin about four times as rapidly as amalgam. More exact figures will be given later. These relations exist only where the surfaces are all equally exposed to friction. We shall see that under the simultaneous action of acids and friction, a very different result is produced.

Pink gutta-percha offers practically the

same resistance to the action of brush and powder as enamel.

With regard to the question above proposed in the Brausewaldt case, I determined by restoring the contour of the amalgam filling, taking measurements before and after, that there had been a loss of substance amounting to 0.7 mm., or about the same loss as was produced in the middle of the filling C by seven hours' brushing. This corresponds to a loss of 0.34 mm. of enamel at its thicker part, B (*c*) and of 1.50 mm. in the dentin, B (*a*). The amalgam filling was two and one-half years old, and we conclude, accordingly, that in this case of Brausewaldt's the patient used friction enough to wear down the enamel 0.34 mm., and the dentin 1.50 mm. approximately in two and one-half years.

BEHAVIOR OF TARTAR UNDER THE WASTING PROCESS.

The appearance of tartar on teeth suffering from wasting may sometimes furnish a clue to the nature of the process.

FIG. 15.

Showing effect produced upon tartar under the wasting process.

In Fig. 15 we have, for instance, a case of wasting in which the tooth is incrustated with tartar, and the tartar is cut in a

plane perfectly flat with the surface of the tooth. We have in this fact evidence that the wasting has been caused by some rigid body, since my experiments have shown me that a tooth-brush rounds off the margins of the tartar; but I shall return to this point later on, under the heading of mechanical action in conjunction with acids.

ACTION OF FOOD AND OF CRYSTALLINE BODIES IN THE SALIVA.

I have already referred to the wearing down of the teeth both of men and of animals by the habitual use of food containing hard or gritty substances. We know that in the course of years the teeth may be considerably worn even under an ordinary diet. The question naturally arises whether the friction of food upon the facial and lingual surfaces of the teeth may not also wear away the enamel and dentin. My studies in relation to this question have convinced me that any loss of substance from this cause is under ordinary circumstances a negligible quantity. How slight this friction of the food upon the facial surface of the teeth is, may be seen from the fact that it barely suffices to keep this surface free from precipitates, greasy deposits, etc., especially at the necks of the teeth. Still less does the friction of the lip or cheek alone have any wearing effect upon the teeth.

The idea has also been expressed that certain crystalline substances normally present in the saliva may assist in wearing away the teeth. By brushing a molar for three hours with crystals of acid calcium phosphate moistened in water, a considerable wearing away at the neck and roughness of the enamel were produced. The surface was not quite dull, but it lacked the characteristic high polish. The mechanical action of the crystals was here modified by the acid action. We are not quite sure, however, that the acid calcium phosphate occurs in the oral fluids; if it does, we shall find it in solution. It will be chiefly the in-

soluble phosphates and possibly oxalates that come into consideration here. These we will find in a condensed form in the deposits upon the teeth (tartar). By the use of powdered tartar on a brush I was able to wear a slight groove in the neck of a tooth in four hours. No action upon the enamel could be detected; brushing with saliva had no appreciable effect beyond polishing of the surface possibly, with a nominal loss of substance. We need not fear that we may be going wrong in attributing but very slight importance to agencies of this nature.

MECHANICAL ACTION OF CURRENTS OF SALIVA.

Mr. S. P. Mummery has suggested the possibility that channels may exist in the mouth formed by the margin of the gums, along which currents of saliva flow and gradually wear away the teeth after the manner of the dropping water wearing away the rock. But neither Mr. Mummery nor I found any action when a fine stream of water from the hydrant was allowed to strike upon a tooth for seven days in succession. I imagine, however, that I am right in supposing that it is only because the running water conveys occasional grains of sand, that the rock is gradually worn away. We must conclude, accordingly, that currents of saliva can have no effect upon the teeth, unless they carry some gritty substance with them. In such cases, undoubtedly, the teeth might show a slight superficial wearing in the course of time, as is demonstrated by my experiments.

A jar holding ten liters was filled with water and about half a pint of pumice added. From this, by means of a syphon, a fine stream of water was made to fall upon the surface of a tooth. In two weeks no loss of substance could be detected, but the surface was highly polished, thereby indicating a certain amount of mechanical action. It should be noted that the stream of water did not carry pumice all of the time. As often

as we thought of it during the day one of us stirred up the pumice, but in about ten minutes it had again settled to the bottom of the jar, so that the actual amount of time during which the stream of water carried pumice was comparatively small. In a second experiment a number of teeth were inclosed in rubber tubes, with a hole about one-quarter inch in diameter cut so as to expose the dentin and enamel. The teeth were placed in a small flask containing powdered pumice in water, and fixed to a wheel revolving at the rate of ten revolutions per minute. In 100 hours a slight but still distinctly perceptible wearing of the dentin had taken place.

Finally, two teeth were fixed with sealing-wax in a glass tube twelve inches long, parallel to each other and across the tube, with a space of about 2 mm. between them at the neck. The tube, having been partially filled with water containing corundum powder, was rotated as above, end over end. The mixture rushing back and forward through the slot produced a slight wearing away and polishing of the surfaces. The time was not noted. In the absence, however, of appreciable quantities of gritty substance in the saliva under normal conditions, it becomes apparent that this factor also deserves but little consideration in the search for the causes of wasting.

ABSENCE OF WASTING IN POLIKLINIK PATIENTS.

Parreidt has made the statement that among patients of the Leipzig Poliklinik, wasting has been observed only once in 30,000 cases, and others have made similar observations.

During my earlier experience in the dental department of the University of Berlin, I found that severe cases of wasting were almost unknown among the class of patients that applied for treatment there. Occasionally I saw a case of wedge-shaped defect at the neck of the tooth, but I invariably found in such cases that the patients brushed their teeth

diligently with prepared chalk, which we have seen is quite sufficient to wear grooves at the necks where the teeth are denuded. I recall only one case in which there was a destruction of the enamel, and in this case, the patient being forty-five years of age, in perfect health, and particularly free from gout or rheumatism, had brushed his teeth for many years with cigar ashes and powdered oyster-shell.

The comparative absence of wasting among these patients is accounted for by the fact that very many of them have but recently begun to use the brush, and none of them can afford the fancy tooth-powders and pastes which are so destructive of tooth-substance.

It is, however, a very significant fact that wedge-shaped defects are now gradually becoming more frequent among our patients. This I can readily account for, as many of them have attended the clinic regularly for a long series of years, and have acquired the habit of brushing their teeth daily with powder.

We occasionally read, in the dental journals, of cases of wasting in which it is stated that the tooth-brush has never been employed, and these instances have always been made use of against the mechanical theory of wasting. To this I may reply that such cases, if they occur at all, are extremely rare. Among the ninety patients whom I have examined within the last few months, there has not been one who has not used the tooth-brush, and all of them but one employed powder at the same time. In this one case, the patient, a man seventy years old, said that he had been using tooth-soap for many years; previous to that time, however, he had used powder. The case to which I wish to refer in particular is one reported by Ivy in the *DENTAL COSMOS*, 1902, vol. xlv, p. 929, a case of wedge-shaped defect at the necks of the teeth, extending more or less upon the labial and buccal surfaces. There are two points which have been made in respect to this case, and which are supposed to argue against the tooth-brush.

In the first place, the teeth of the upper jaw were free from wasting, but as we

are told that these teeth were perfectly healthy and protected by healthy, firm gums, it is difficult to see how wedge-shaped defects could originate, and it is no uncommon thing to find the teeth much more wasted in one jaw than in the other, even where there can be no question as to the mechanical origin. In the second place, this patient is reported to have said that he had not used a tooth-brush for fifteen years. At the same time Dr. Ivy tells us that on the second visit, five years later, the wasting had not extended in any one instance, which simply shows that at the time being there was no wasting going on, and as the patient was not using a tooth-brush this can be readily understood. In all probability the wasting was a case of very old standing, and we are justified in drawing no conclusion whatever, unless we can prove that the patient did not make use of the brush previous to the period mentioned. In fact, the statement that he had not used the brush for fifteen years shows that he did use it before that time. This, together with the fact that the wasting was not going on at the time being, makes the case an argument in favor of the brush.

I have a number of cases of wasting which have been stationary for many years, and which owe their origin to the use, years before, of some powder containing pumice or oyster-shell. A case in the practice of Dr. Abbot, in which the condition bade fair to destroy nearly all of the teeth, which I had the privilege of examining a few days ago, has remained *in statu quo* since Dr. Abbot ordered a mild tooth-powder and a brush of badger hair.

WASTING OF THE TEETH IN UNCIVILIZED RACES.

We must in passing also refer to the question of wasting in races that do not use the tooth-brush, or an equivalent. In the year 1884, I examined all of the skulls in the Berlin anatomical museum, and did not succeed in finding a single case of undisputable wasting. But little

has been done in the study of this phase of the question since my publication. The late Zahnarzt Stieren of Wiesbaden wrote me some two years ago that he had examined twenty skulls with negative results. More recently Mr. S. P. Mummery of London has gone through some of the collections there, and confirms the above results in a letter just received. The testimony of Dr. Grevers of Amsterdam is particularly significant in this connection. During his studies, which have extended over many years, he has examined no less than 6000 old skulls, and he informs me that he did not find a single case of wasting among the entire number.

In examining collections of skulls in reference to this question, one must naturally avoid the mistake of putting down the deformations practiced by some races to the score of wasting. Also it must not be forgotten that certain races, that may be classified as non-civilized, still care for the teeth, using the well-known twig as a tooth-brush.

WASTING OF THE TEETH AMONG THE JAPANESE.

Considerable interest was aroused by a communication of Dr. Ottofy of Manila, at the Fourth International Dental Congress, printed in the DENTAL COSMOS, 1905, vol. xlvii, p. 71. Dr. Ottofy attributes the prevalence of wasting among the Japanese to the fact that they use human excreta for fertilizing their vegetable gardens, and believes that the small stature of the Japanese is to be accounted for in the same way. No proof beyond conjecture could be brought forward in support of this view, and after the exhibition of bodily activity and endurance on the part of the Japanese in the late war we cannot well accept the hypothesis that they have been brought up on poisoned food.

In particular	evidence in
‘h	wasting of
	condition
	easy to
	t without

having had the opportunity to study it personally. From Japanese residents in Berlin I have received some information bearing on the point. I am told that the Japanese care for their teeth very diligently in the cities, using the tooth-brush, and in the country to a considerable extent still the wooden twig hammered out at the end to a bundle of fibrils. Mr. Teranoki says that while there are very many people here in Berlin who never brush their teeth, which is quite true, everyone does so in his country. Finally, I have obtained a sample of tooth-powder manufactured in Tokio and formerly used in Japan, which quite equals the famous Chinese tooth-powder in its roughness and its action upon the teeth.

(See Fig. 5, C.) Possibly investigations in this direction may throw some light upon the question of tooth-wasting among the Japanese.

As a result of the above experiments and studies, I have been more and more confirmed in the opinion that the majority of cases of wasting met with in daily practice are due chiefly to the action of the brush in conjunction with tooth-powder, and that compared with this one, other mechanical agents are of minor importance. The question now arises, What are the chemical agents which may be concerned in the process, and to what extent are they responsible?

(To be continued.)

SUPPLEMENTARY RETAINING FORCES AS AUXILIARIES TO THE LABIAL RETAINING APPLIANCE.*

By CALVIN S. CASE, D.D.S., M.D., Chicago, Ill.

IN a paper entitled "Principles and Technics of Retention in Orthodontia," read before Section IV, Fourth International Dental Congress in 1904, and published in the DENTAL COSMOS in its issue for June 1905, the author endeavored to arouse an appreciation of (1) the difficulties that are liable to be encountered in the retention of regulated teeth; (2) the importance of a thorough understanding of the principles of occlusion upon which the retention of regulated teeth is largely dependent for its permanence, and (3) the importance of exercising great care and skill in the construction of retaining appliances which are destined to be worn for a year or more, and frequently during longer periods, without examination or readjustment.

In the above-mentioned essay, of which this paper is a continuation, and in former papers, was described a labial retainer that has been in use in almost every case in my practice for the past ten years. It has therefore been well tried, and I wish to say at this time that were I deprived of its use the successful practice of orthodontia would be considered by me impossible.

This retainer, as shown in Figs. 1 and 2, will perhaps be recognized by some of the Chicago delegation, who doubtless have been given an opportunity to examine one or more of these appliances out of hundreds that have been and are still being worn by their patients. If so, I trust they will be willing on this occasion to attest to their perfection. They not only hold the teeth firmly, but are by far the

*[Dr. Case was on the program to read this paper before the last meeting of the National Dental Association. It was to have been illustrated with twelve specially prepared lantern slides, but was withdrawn because there seemed to be no opportunity to present it with the slides.—Ed. COSMOS.]

least conspicuous of anything that has yet been constructed which firmly grasps and immovably retains the teeth to which attachment is made. They, moreover, are fitted so closely to the teeth, with freedom from irritating prominences, that they

FIG. 1.

are willingly worn any length of time, the only requirement being that they shall be examined occasionally, and if found loosened in the slightest degree, removed and re-cemented.

After the correction of nearly all simple and complex irregularities, and also in classified irregularities, if the above six-band labial retainer be properly con-

FIG. 2.

structed and attached, it will commonly be found sufficient in itself to perfectly retain the teeth, even though the buccal teeth, which may have been considerably moved, are not involved in the grasp of the fixture. This of course presupposes that the upper and lower teeth have been brought to the desired relative positions, and that the cusps of the buccal teeth perfectly interdigitate, though perhaps not in typically normal occlusion. There are, however, a number of important supplements to this appliance which will be demanded for the retention of extensive movements.

RETENTION OF LATERAL EXPANSIONS.

If one arch has been laterally expanded to the desired occlusion with the normal opposing arch which has not been moved, the simple six-band labial fixture shown in Fig. 1 will usually retain the expansion and any changed curve or mal-alignment of the labial arch. But if the operation has been performed without due regard to the forces of occlusion, and the opposing arch has been allowed to remain laterally contracted, the stability of these unmoved teeth will surely drive the expanded teeth back to their former position. This force of occlusion will frequently be sufficient to bend or displace

FIG. 3.

any labial retainer that is not of unusual proportions, and will finally complete the failure of the operation after the retainer is removed. When both arches have been laterally expanded—as they should be in the last-named condition—and if the lower expansion be supported with a clasp-metal bow No. 16 or 14 soldered to the lingual face of the six-band labial retainer as shown in Fig. 3, the forces of occlusion in connection with the regular upper labial retainer shown in Fig. 8 will usually be sufficient to hold both arches in position.

With certain occlusions it may be found expedient to attach the lingual bow to the upper arch instead of to the lower, and in some instances to both. The length of the arms and the size of the wire for the lingual bow will be governed by the demands of the case. If the distal area has been much expanded, with a demand that the arms extend to the molars,

they should be supported by thin lingual tubes soldered to No. 36 gold molar bands, and with every precaution in finish, for cleanliness and non-irritability.

RETENTION OF RETRUSION MOVEMENTS.

When all of the upper or lower labial teeth have been retruded to reduce decided protrusions and to close spaces occa-

FIG. 4.

sioned by the extraction of bicuspid, the labial retainer should carry thin No. 19 tubes soldered to the linguo-distal borders of the canine bands as shown in Fig. 4, for the purpose of attaching the appliance to the molars, either at the start or upon the first indication of a return movement. The traction bars are of either No. 19 or 20 German silver, provided with distal nuts, as shown in the drawing, or preferably with mesial and distal nuts, to firmly lock them in the lingual tubes attached to gold molar bands. This will enable one to keep all interproximal spaces closed, and if at this time the occlusion be perfected, it will be found sufficient. In many cases in which the age of the patient and the position of the teeth, etc., favor permanence of retention, the lingual bars and molar bands are not at first attached, though the lingual canine tubes in these cases should always be placed in the construction, to be employed if found necessary. These tubes being small and lying close to the gum, when properly finished give no irritation or annoyance.

INTERMAXILLARY RETENTION.

In cases which are purely protrusions of the upper teeth, to the extent that the buccal cusps interdigitate fully the width of a bicuspid in front of a normal occlusion, and which should usually be corrected by the extraction of the first or second bicuspid, the buccal teeth in the course of the operation—if employed as the sole anchorage force for retruding the labial teeth—may be forced slightly forward of an interdigitating occlusion, and then, if employed as in Fig. 4 as the sole means of retention, will tend to be dragged farther forward by the reacting force of the front teeth. Or it may be one of the many cases in which in its original state the upper teeth in relation to the lower teeth were protruded, perhaps to the extent of a full width of a bicuspid, but which according to dento-facial relations was found to be due partially or wholly to a retrusion of the lower denture, and consequently corrected with the intermaxillary force without extraction. In both of these events, hooks of No. 28 clasp metal are soldered to the labio-distal surface of the canine bands, and formed to protect the bicuspid from

FIG. 5.

the action of the elastics, as is shown in Fig. 5.

In all cases where the intermaxillary force has been extensively employed for the disto-mesial correction of malocclusion, nothing but a continuation of this character of force in a milder degree seems capable of retaining the position gained, notwithstanding the fact that the teeth at times have been brought to perfect or normal interdigitating occlusion.

Moreover, where the final movements for the disto-mesial correction of malocclusion can be accomplished with the intermaxillary force alone, the labial retainer as described may be attached for this purpose as soon as the six anterior teeth are corrected in relation to each other.

LOWER INTERMAXILLARY ANCHORAGE METHODS FOR RETENTION.

In determining the character of the lower appliances for using the intermaxillary force, warning cannot be too often repeated in regard to the care that should be exercised in the application of a mesial force through this medium from opposing teeth; as the same rules here obtain as in major movements. These are in the main—

First: When no mesial or extruding movement of the buccal teeth is desired, the anchorage hooks for the elastics should be placed at the most distal points possible, and attached to a two- or three-band stationary anchorage. (Fig. 5.)

Second: If a mesial movement be desired and the extruding tendency of the elastics be feared, the intermaxillary hooks should be attached to the most

FIG. 6.

distal points of single molar bands—preferably to the second molars—which are anchored down with No. 19 or 18 bars, the distal ends of which rest in short tubes upon the anchor molars, and pass forward, under hooks or through short open-tube attachments on the first molars and bicuspid teeth, to rest upon the canines. (Fig. 6.) All of these bands should be as thin as the desired strength will permit. With this combination the extruding force upon the anchorage will

be inhibited by distributing the extruding force to all the buccal teeth, while a mesial tipping of the crowns will be permitted through the possibility of the contact points sliding upon each other. If an arch bow be employed instead of the bars, the incisors may also be attached to it if desired.

Third: If the extruding movement be desired, following the correction of

FIG. 7

a short or close-bite malocclusion, the elastics should be attached to the single *first* molar bands or to the crowns which were employed to open the bite, and the balance of the apparatus so arranged as to distribute the force to the bicuspid teeth. In a large proportion of these cases the lower arch and mal-aligned or mal-turned incisors have been corrected, demanding the employment of the six-band labial retainer. In these instances it is frequently desirable to directly connect the lower labial retainer to the intermaxillary anchorages, which enables an even distribution of the protruding force to the lower front teeth and a complete relief to the bicuspid area, so that these teeth will not be crowded out of line by contact pressure. This is one of the common methods employed by the author in the mesial action of the intermaxillary force upon the upper or lower arch when the front teeth are in alignment. (Fig. 7.) To the labio-distal surfaces of the canine bands of the retainer are soldered flattened tubes which are bent to receive the mesial ends of No. 18 or 19 bars, the distal ends of which are locked, with mesial and distal nuts, in buccal tubes upon the first molar bands or crowns. When the intermaxillary elastics are looped over the distal nuts, or attached to special hooks, the force may be distributed directly to the labials in phalanx.

The bars may also be employed to correct or retain the bicuspid.

The most common malocclusion, for which the intermaxillary retainer is especially applicable, is that in which the upper buccal teeth have been moved distally, and the lower have been moved mesially to a normal occlusion, and corrected without extracting. If the forward movement of the lower teeth has not been sufficient to produce an abnormal labial inclination of the front teeth or to force them out of alignment, the intermaxillary buccal anchorages for elastics to the upper labial fixture, as in Fig. 5, will usually be found sufficient to retain the occlusion, though when a still further forward movement of the lower teeth is desired, the methods shown in Figs. 6 or 7 will be indicated.

Where the lower teeth have been moved forward considerably with the intermaxillary force, it is presumed that the incisors have usually in movement been kept bodily in an upright position with the contouring apparatus. Upon removal of the regulating appliances, the contour retaining apparatus (Fig. 11, described later) should be attached to the lower, in connection with the intermaxillary labial retainer upon the upper. It is perhaps needless to say that when the upper and lower conditions are reversed, the same apparatus reversed will be equally applicable.

The amount of intermaxillary force to be applied during the period of retention should be governed by the needs of the case. It should not be at any time in excess of a force that is sufficient to retain the position gained—that is, providing the teeth are fully corrected when the retainer is placed—as this would necessitate stopping the force every once in a while and allowing the teeth to go back, and it is this swinging back and forth in the sockets that is especially opposed to the formation and solid fixation of permanent retaining alveoli. It is far more advisable that the weight of the elastics be gaged to a degree that will hold the teeth perfectly while they are being worn continuously. Faber No. 5 (ticket rings) are the same size in circumfer-

ence, but only about one-half the weight of No. 6 (election rings), of which single and double are commonly used for regulating. No. 7 (thread bands) are the same weight as No. 6, but being about twice the size will exert less intermaxillary force than No. 5.

I frequently correct the labial malrelations of the arches and place the front teeth in proper arch alignment then make the retaining apparatus as above before the disto-mesial malocclusion is corrected, knowing that the intermaxillary force can be gaged to any degree, and that it will act quite as perfectly in retaining or in moving the teeth, if properly applied, as with the regulating device. The teeth are not so liable to be forced out of alignment, and the appliance is far less conspicuous than the usual regulating appliances; while the rigidity of the retainer, holding the labial curve of the arch in its corrected position, is of the greatest aid in preventing the reactive forces from laterally contracting the entire arch.

DIRECT INTERMAXILLARY RETENTION.

The correction of extensive open-bite malocclusion has always been the most difficult to retain of any of the characters of irregularity, because of the impossibility in most cases to obtain a stable hold upon which to anchor the retainer that would successfully combat the force of reaction. Where a lingual or labio-buccal bow is anchored to the molar teeth for this purpose, the reactive forces upon the open-bite labial teeth tending to intrude them will usually force the distal extremities of the bow and anchorages in the opposite direction, extruding the molars, which in itself will open the bite still further, as any movement at this point will be magnified in its action upon the front teeth. The intermediate teeth also, which are employed in this method as fulcrums to the elastic force of the bow, are frequently intruded.

These difficulties are now overcome by soldering small spurs to the upper and

lower labial retainers, as shown in Fig. 8. To these are attached direct intermaxillary elastics by the patient, which are worn continuously at all times when not interfering with required functions. This force should be continued until the

FIG. 8.

forces of reaction are completely overcome. As a large proportion of these cases are mouth-breathers at the time of the operation—the habit having continued long after the causes are removed—the elastics also subserve the purpose of aiding the patient in overcoming this unhealthy habit.

OCCIPITAL RETENTION.

In the correction of many cases of decided upper protrusions—especially those in which the incisors are in an extruded position and thus in unpleasant evidence in relation to short upper lips, and particularly in close-bite malocclusions—the

FIG. 9.

occipital force, with its backward and upward direction of movement, has proved an indispensable auxiliary in the author's practice. Again, in the correction of open-bite lower protruded malocclusions, the occipital force applied to the lower labial teeth is one of the most valuable and effective forces for closing the bite, and for aiding in the retrusion and extrusion of the labial teeth after the extraction of bicuspid.

In both of these characters, the tendency of the reactive forces is often difficult to overcome for a time with den-

tal retainers alone. Nor does one always obtain the full desired results of these movements at the time when everything else is finished and ready for the usual retaining appliances. In these cases, therefore, a No. 18 iridio-platinum wire is soldered to the interproximal extensions of the six-band labial retainer, and in such a position as to span the central incisors as shown in Fig. 9. The bar, which crosses well above the medium extension of the appliance, forms a perfect rest for the occipital bow A on the upper, and bow B on the lower. Small rings soldered to the bar on each side of the lips of the rest prevent lateral motion. This occipital apparatus worn at night and with a moderate degree of force will give little or no annoyance, and will exert an evenly distributed force upon all the labial teeth to which the retainer is attached. In many cases for which it has been employed in this way, it has accomplished results that the author believes would have been otherwise impossible.

RETENTION WHERE TEETH HAVE BEEN MOVED BODILY.

In the contemplation of retaining teeth which have been moved bodily, the magnitude and peculiarity of the force of a lever of the third kind, which has caused the apical ends of the roots to move, is quite as important to consider as the direction of the movement. The retaining appliance capable of fully sustaining this movement must be one that will forcibly combat the great reacting tendency of the elastic bone-fibers of the alveolar process to return to equilibrium. As this force is exerted along the entire length of the root, it is evident that the stress upon the comparatively narrow zone of the crown which is grasped by the retaining appliance increases as the force approaches the apical end of the root—on the principle that the advantage of a lever of the first kind is increased by lengthening the power arm. Therefore the necessity is apparent, in this character of retention, of employing distally extended arms which are exceedingly rigid in quality, and attachments to the re-

tainer. This is especially true of bodily protruding movements of the labial teeth, which so commonly carry the entire alveolar ridge forward in a manner that could not be accomplished other than by bending and stretching the cancellous structure of the alveolar process at the apical zone of its attachments. With bodily retruding movements of the labial teeth, the obstructing process in the pathway of the moving roots is more largely resorbed, and consequently they are far more easily retained.

When a bodily protruding or retruding movement of the incisors has occurred, which has not been accompanied by a movement of the roots of the canines, the six-band labial retainer, attached firmly as it is to the canines, will greatly aid in retaining the root-movement of the incisors, though it should always be supplemented with rigidly attached lingual bars to the molars. Fig. 10 represents the common retainer employed in these cases. Rigid No. 14 bars are screwed into long-bearing tubes soldered to the

FIG. 10.

lingual surfaces of the regular six-band labial retainer. The bars rest in lingual molar open tube-attachments with lock nuts to insure stability. In the final assembling and placing of the appliance the bars are bent up or down, so that when sprung into the tubes they will exert a slight extra force upon the roots in the direction of their movement; then the anchorage tubes are closed around the bars and the projecting edges and corners

are smoothed to prevent irritation of tissues. In addition to retaining the teeth, the forces of movement may be increased by bending the bars and turning the nuts.

Where extensive protruding movements have been produced, the incisor bands of the labial retainer should be sufficiently wide to cover the entire lingual surfaces,

FIG. 11.

to which they are perfectly fitted, in order to produce a wide and perfect grasp upon the crowns. When rigid bars are firmly attached to these long bearing bands and the ends sprung into open tube-attachments on the molars, they exert a "pull" force at the incisal zone and a "push" force at the gingival zone, which is transmitted to the entire root, as shown in Fig. 11. In connection with this, if the ends of the bars are threaded for mesially acting nuts, the appliance can be made to exert a similar—though less powerful—force to that of the regular contour apparatus. (Fig. 11.) Because of its inconspicuousness it may be preferably employed from the start in minor bodily protruding movements of the incisors: Also in all cases where it seems desirable to remove the regular apparatus before the full completion of its work, it will be found invaluable for holding the position gained and for continuing the movement. This apparatus is described as follows:

The contour protruding retainer shown in Fig. 12 is constructed with a view to combat the reaction of root-movement, also to continue this force, and if necessary the bodily movement to a slight degree. To the lingual surface of the labial retainer, instead of the usual enforcement plate, is soldered a German silver or, preferably, a clasp-metal wire bow, No. 13 or 14. The contact surfaces of

the bow are filed to fit the lingual surfaces of the bands. In attaching the bow to the labial bands an abundance of solder should be flowed well over the lingual surfaces of the bands to reinforce their stability and to remove from the surface irritating prominences. The distal ends of the bows are threaded to lie in open lingual tubes upon molar anchorages, which are provided with buccal intermaxillary hooks. The same care should be exercised in fitting the bow to lie along

final placing, while the protruding force will be otherwise controlled by the nuts at the mesial ends of the tubes. If at any time it is desired to increase or reduce the protruding force upon the roots of the labial teeth, the bow can be easily bent with the curved wire benders shown elsewhere. The intermaxillary force is an important auxiliary in sustaining the stability of the anchorages, and as an aid toward a general protrusion of the upper teeth and retrusion of the lower.

FIG. 12.

the lingual surfaces of the teeth, and the ends to lie evenly in the tubes, as was described in fitting the power bow in the regular contour apparatus. Finally, with this apparatus the ends of the bow are bent, at the points where they join the labial retainer, toward the occlusal plane (see Fig. 11), so that in the final assembling after the cement has hardened, the ends are sprung toward and into the open tubes, which are then closed around them. The distal ends of the tubes and bow should be beveled and finished to present no irritating surfaces.

In Fig. 11 the bicuspid are removed from the drawing to show the lingual bars. The dotted lines and arrows indicate the principles of action. It will be observed that the spring of the bow, in combination with the rigidly attached labial retainer, is calculated to exert a protruding force upon the roots. This force will be in proportion to the amount of bend that is given to the bow in the

When this apparatus is employed principally for bodily protruding the incisor teeth—as it may be in all minor cases, with the view of subsequently forcing the canines and first bicuspid forward by inclination movement with push bars from the anchorages, or with the production of a mesial movement of all the buccal teeth with the intermaxillary force—the incisors should first be placed in relative alignment, and the four-band labial retainer should be constructed with the lingual bow attached, etc., as described above. If the canines and first bicuspid are to be moved forward with the view of inserting an artificial bicuspid to sustain the arch, buccal tubes should be soldered to the anchorages for No. 18 push bars, to be employed for this purpose later in the operation.

The unusual enthusiasm in the practice of orthodontia which has arisen in the past five years—largely through the recently created impression that the regu-

lation and retention of teeth is an operation that can be easily accomplished with very simple appliances—has perhaps by this time become somewhat cooled under the tests of experience, and therefore we may hope for a more willing acceptance

of long-tried principles and methods, which because of their greater complication appear to demand a higher order of mental and physical training, but which I am sure will be found in the trend of true success.

THE PORCELAIN ROD IN DENTISTRY.*

By GEO. B. MITCHELL, D.D.S., Buffalo, N. Y.

(Read before the Dental Society of the State of New York, at its annual meeting, held at Albany, N. Y., May 11, 1906.)

THE subject of porcelain has been the leading topic at dental meetings and clinics during late years—to such a degree that many present may, no doubt, think that the field of porcelain obturations has been thoroughly and exhaustively covered the world over. Yet porcelain work today is enjoying but the childhood of its existence.

It is granted by most of us, I trust, that porcelain operations have been definitely accepted as a valuable and an obligatory branch of dentistry. Thousands of our profession are marching onward with the work, and hundreds are actively engaged in experimental studies; and it is without question that no branch of our professional calling has called forth such an abundance of consideration as has porcelain work in its many forms. Especially is this evident when in addition to our own professional enthusiasm we consider the amazing amount of knowledge of this work and its esthetic results, shown by the laity, and their demand for it.

In an exhaustive reading of society proceedings, society papers, and journals, and in attendance upon many of the important meetings of the East, during the past five years, the writer has discovered that with all our eagerness for porcelain data, the profession as a whole has not been brought in touch with one of the

most valuable aids in porcelain obturations; namely, the system of round porcelain rods for the filling of *certain*—yet numerous—cavities found in the *dentes adulti*; the matrix-fused porcelain being the only method which has engaged our attention to any extent.

General considerations. The porcelain rod inlay differs from the fused porcelain inlay in these particulars: No matrix or special model is required; the work is perfected in the mouth, the original model. The bur last employed serves as the model, and the contour is obtained by grinding away the surplus after cementation. No furnace for baking is required; the porcelain is already fused. Also the greater ease of preparation of both cavity and inlay.

Advantages. It may be advisable at this point rather than in conclusion, to note the cardinal benefits which this system renders, which, you will see as we progress by means of the charts, are present in each and every operation.

First: The cavity preparation in this system is an absolutely perfect cavity preparation, as our standard of today informs us—namely, a flat base with parallel or nearly parallel walls. We all know the first requisite for success in porcelain work is proper cavity preparation.

Second: The porcelain rod inlay, in

*Many of the illustrations accompanying this paper have been reproduced from the issues of Ash's *Quarterly Circular* for 1904.

cases where its employment is permissible, is not surpassed by any other method in operative dentistry, as regards esthetic appearance, simplicity of construction, and security.

Third: In its place, it is the most rapid and accurate method, producing the most satisfying results of any operation with which we have to deal.

Fourth: The cement line is practically nil. The writer has seen many a finished operation in which he doubts if the binocular microscope could find a cement line, although Dr. Joseph Head in relating his experiments tells us that the complete obliteration of this line is impossible. The reason for this "no line" will be shown later.

The foregoing statements are strong ones, but the writer feels sure that you will substantiate these claims as we proceed to the end of the paper; if not then, surely after having experimented with this procedure.

The only great drawback from making the porcelain rod the ideal filling of today is the limitation in the situations where it can be inserted.

Acknowledgment. Dr. Alfred Guttmann of Potsdam, in a very able manner (see Ash's *Quarterly Circular* for 1904) has covered this field exhaustively, and it is with his very kind permission that I draw upon his essay and correspondence for a large part of this paper.

History. Ground fillings date as far back as 1820, when Linderer endeavored to insert ground fillings in the teeth. For this purpose pieces from the tusk of the walrus and hippopotamus were ground to approximate the cavity preparation, and then pressed into place; the saliva coming in contact with the stopper made it swell, thereby perfecting the marginal closure and security of the plug. This method in later years received severe condemnation; the subject will not here be discussed.

Later, the grinding of porcelain tips and pieces from artificial teeth was recommended in 1855 by Volk, followed

by Wood, Hickman, and finally Dall. This method is familiar to all, and is used in some cases at the present time, but it is a laborious process.

To facilitate and simplify the shaping and fitting of porcelain pieces, the use of fused porcelain inlays and rods was later inaugurated by Dall. How, Sachs, Pierre Robin, Allen, and Guttmann have each a method of his own, and it is in the development and consideration of their respective methods that the writer begs your indulgence.

Dall's Method. Dall first facilitated the manipulation of porcelain pieces by constructing round, square, pear-shaped, oval and other forms of fused porcelain rods—thereby approximating the cavity outline more closely—and finished by grinding the inlay, cavity, or both, until adaptation was perfect or nearly so.

Fig. 1 shows Dall's manufactured rods—A, for cavities at the cervical border; B, C, D, for cavities in the labio-distal and labio-mesial surfaces; E, F, G, H, for cavities in the labial, buccal, and occlusal surfaces.

Dall's further improvement was to prepare every cavity circular, thereby facilitating the operation and systematizing the result by using circular porcelain inlays exclusively.

Dall's method consisted, first, of twenty-five circular tapered burs (Fig. 2), the sizes being graduated one to the other: Secondly, a gage in which there was a series of holes, each numbered hole corresponding to the respectively numbered bur, which will fit it accurately. (Fig. 3.) Thirdly, specially manufactured circular porcelain inlays, in two thicknesses, shallow and deep, varying in shades. These inlays are cross cut on the bottom for cement retention, the deep ones having in addition a gutter around them near the base, providing additional anchorage. (See Fig. 4.) A stud on the outside facilitates handling.

Technique. The technique, which is nearly the same in all methods, consists of the removal of decay, approximating

at the same time a circular form, starting with a bur either just the size of the excavated cavity or else smaller, and gradually increasing the diameter by the

edly due to the immense number of prepared inlays of various colors that one would of necessity be required to have on hand—some hundreds, in fact, to have

FIG. 1.

FIG. 2.

FIG. 4.

FIG. 3.

respective burs until the proper outline is obtained—namely, upon sound tooth-structure. The bur must be held *positively* at right angles to the floor of the cavity. The last bur used gives the size of the inlay needed, via the gage. The cavity is undercut and the inlay cemented. Dress down the excess of inlay and cement, at the next sitting.

The non-use of this method is undoubt-

an assortment of any value. Coupled to this is the fact that the manufacturers have not aided us by stocking a proper supply (perhaps for the same reason), and one must necessarily send to England for replenishment.

How's method. The cavity preparation is the same as in the previous method. The inlay, however, is ground from a porcelain tooth, of the proper

shade, to approximate the circular cavity. (Fig. 5.) This piece is shellacked to

FIG. 5.

a metal mandrel fitted in the handpiece and allowed to run over a carbo file until quite round (Figs. 6 and 7), when it is

FIG. 6.

cemented as before. Objections are the length of time consumed in the manipulation and the two or three sittings necessitated.

is a more expeditious operation, but also requiring dexterity and attention.

Pierre Robin's method. The instrument outfit for this method consists of eleven cone-shaped burs, to be used in the straight and right-angle handpieces. Arranged in consecutive order endwise against one another, they form a cone—the thickest part of the smallest bur corresponding to the thinnest part of the next larger one. (Fig. 8.) The curve $a-b$ shows the size of bur No. 1; $a'-b'$, bur No. 2; $b-c$, bur No. 3; $b'-c'$, bur No. 4, and so on.

Porcelain rods are made to correspond to this cone, being so formed that each bur corresponds to some one part of each rod.

This is the first introduction of the

FIG. 7.

fused circular rods, and Figs. 9 and 10 show some of Robin's cavities. In these figures we cannot agree at points x —as the enameled rods would be so under-

FIG. 8.

Sachs' method. This differs from the foregoing only in the fact that the inlay is ground on the lathe-stone. It

mined as to be extremely dangerous. It can be advantageously used, however, as in the Guttman method and with the

Dall gage, as will be seen later. In Fig. 11, cross section, all the walls are

ning to a cone, very gradually increasing in size; the large end of one bur corre-

FIG. 9.

FIG. 10.

FIG. 11.

intact, and in such pitted teeth (hypoplastic and rhachitic teeth) this is the ideal filling, the cavity passing through the lingual wall. We will see later how Guttman improves upon this.

sponding to the small end of the next bur, and so on. In manipulating the burs they should be allowed to feed themselves, no pressure being exerted, cutting at short intervals rather than steady

FIG. 12.

Guttman's method. This is an improvement on all preceding methods, with one small exception, as Allen's, to be shown later.

The burs are shown in Fig. 12, *a*, in contradistinction to Dall's, *b*, by being longer—thereby more accurately producing good margins in deep cavities. The burs, circular in form, are finely cut as a finishing bur, having flat base and run-

pressure, and above all—avoidance of any lateral deviation, which would destroy the circular form desired.

Fused porcelain rods, ground-edge finish on the periphery and of mathematically trued circular form running to a point, are used, as Fig. 13. They are made of Ash's porcelain body—with the value of which we are all well acquainted. Guttman says of it, "The manipulation

of this material is incredibly easy. It can be ground and cut without requiring polishing; the reason for this lies in

FIG. 13.

the beautiful dense structure, which also causes such fillings to look exceedingly pretty."

Cavities. Guttman classifies his fillings into three classes:

(1) The central ground filling—namely, where a complete circular margin prevails, as Fig. 15.

(2) The nearly central filling—namely, the margin formed is more than a semicircle, as Fig. 16.

(3) The non-central—namely, the margins are a semicircle or less than a semicircle, as Fig. 17.

In Fig. 18, where the cavity overlaps the area of change of color present in the natural tooth, it is difficult to ob-

FIG. 14.

Allen's system. Here let me deviate somewhat. The Allen system is practically the same as Guttman's, except that

tain satisfactory results unless the skill of the operator allow expertness in the manipulating of different colored ce-

FIG. 15.

FIG. 16.

FIG. 17.

FIG. 18.

it furnishes rods which are not mathematically trued (trued rods can be purchased, however), and for truing the same, or for porcelain pieces, Fig. 14 shows the holder, and Fig. 19 the trephines, graduated in size, furnished to do this and produce at the same time the necessary ground edge. Carbo powder is used in grinding.

The Dall gage, already shown (Fig. 3), is used in each system.

ments, or the use of trephines (Fig. 19) in cutting out shaded portions of an artificial tooth. In molars and bicusps (Fig. 20), how much better than an amalgam filling, the usual procedure!

It is my belief that in Figs. 21 and 22 the use of this system is questionable, as the amount of undermined enamel rods presents a dangerous feature. Above all other points in porcelain work we must be conservative, and the writer has been conservative enough to leave this stage untried. It is, however, used considerably abroad.

In addition, cavities where rhachitic teeth are present, as Figs. 23, 24, and 25, are most efficaciously filled as in Fig. 23, cross section. For such cavi-

COLOR.

Note if the inlay is to face the light or away from the light. Buccal and

FIG. 19.

FIG. 20.

FIG. 21.

FIG. 22.

ties this is the only filling. No other filling is so simple, so permanent, so secure, or so tooth-like in appearance. If nowhere else, this is a valuable point for

FIG. 23.

FIG. 24.

FIG. 25.

this method. Fit the rod in the prepared cavity, mark each side (labial and lingual), cut off, groove interior, and cement to place. For this cavity preparation Guttman has given us burs as shown in the first bur in Fig. 12. The use of the rods in cases shown by Fig. 10 is again questionable. Approximal wall not intact.

labial inlays, offering one surface to the light, should exactly match the natural tooth.

In cavities on the mesial side, offering two surfaces to the light, a darker shade must be chosen; if away from the light, a lighter color. Ground porcelain fillings, not having to be "fired," never change color as selected, and if we match

FIG. 26.

FIG. 27.

FIG. 28.

the color of the tooth alone, no matter what the position of the cavity, we achieve surprising results.

The rods may be cut up into inlays of varying thicknesses and kept in boxes ready for use. (Fig. 30.) Fig. 31 shows

FIG. 29.

FIG. 30.

TECHNIQUE.

The technique is well illustrated by Fig. 28. The rod is then placed in the gage, as Fig. 29, nicked on each side or marked by pencil, and cut from the rod.

—*a*, cavity; *b*, depth of bur penetration; *c*, depth to which the inlay should go, and *d*, the finished inlay.

The inlay is ground on the base so as not to touch the floor of the cavity. This insures perfect marginal closure when in-

serted, the inlay fitting perfectly, and if all be correct, theoretically at least we

The inlay prepared, the setting of it is greatly facilitated by shellacking it

FIG. 31.

FIG. 32.

FIG. 33.

should have no cement line. The cement is cut off as by a sharp knife.

The base of the inlay is grooved, for

to a bur end, as Fig. 36, lessening the liability—as when pliers are used—of its slipping away at the critical moment.

FIG. 34.

FIG. 35.

central fillings, as Figs. 32 and 33, for thick inlays, and Fig. 34 for thin inlays.

Fig. 37 shows the proper stones to use in removing surplus; which, by the way,

FIG. 36.

FIG. 37.

Always be positive to introduce cement into the cuts before inserting the inlay into the cavity.

Fig. 35 shows grooving for non-central cavities.

should not be removed until a subsequent sitting; if this be not possible, then not before one and a half to two hours, as there is great danger of dislodging the inlay or tipping and fracturing the edges.

Fig. 38 shows proper stones to produce fissures, etc. A polish by finer grits is not absolutely necessary, as the dense structure of this porcelain, when wet with saliva, produces a very fine result.

FIG. 38.

mal cavities. It may be extensively used in the sulci of bicuspid and molars.

In conclusion let me say: To judge if these theories or methods hold good in practice, one must give them a thor-

FIG. 39.

Fig. 39 shows, at *a*, proper, and at *b* and *c*, improper contour to be the result of grinding.

In a set of thirty-two teeth this system may be conservatively used in eighty-one distinct cavities, not counting approxi-

ough and not an indiscriminate test. The value of this method is greater than one may think, and grows larger by usage. It is simple, accurate, rapid, and scientific, producing *in its place* most beautiful results.

GOLD INLAYS.

By W. B. DILLS, D.D.S., Brooklyn, N. Y.

(Read before the Dental Society of the State of New York, at its annual meeting, held at Albany, N. Y., May 11, 1906.)

IT is with some fear and trepidation that I come before you to present radical and contradictory methods for the preservation of teeth from the ravages of decay. Realizing fully the importance of the manipulative art, which has made American dentistry what it is today you can understand why I, as a young member of this honored profession, should hesitate when I assume to cast or throw aside the keystone to the arch of our temple, and presume to substitute for it a new and more practical key for the maintenance of the arch—namely, that of zinc phosphate over gold foil.

We all know that, in the past, the pioneers in dental art were the men who could manipulate gold foil for the successful restoration of lost tooth-structure; and this was carried so far that success

was largely gaged by the ability to handle soft or cohesive gold for the substitution of lost tooth-structure. That this has been and is generally accomplished is beyond a doubt; but that this accomplishment is the best method for the preservation of teeth in the human anatomy is an open question, and as an individual having only limited experience, I can but feel that it is far from the true and scientific solution of the problem.

In the first place, we are educated for the practice of this our honorable profession in order to save and make useful those organs of the oral cavity with as little pain, suffering, and discomfort as possible to those who place themselves under our care. This being the case, we must take into consideration all the advantages and disadvantages, not only to

the operator but to the patient. And it might be well to consider at this time the advantage to the operator, admitting this preference to be selfish.

I doubt if there be one person present who will not concede the fact that a method to be accepted must possess the marked advantage of being either a time-saving or a remunerative process. As an illustration, we will take a lower first molar, with a mesio-approximal occlusal cavity. If the wall of the cavity be of good strength, the restoration may be accomplished with foil and mallet, with perfect satisfaction to both operator and patient, in from one to three hours' time—admitting that the condensation of the foil is perfect.

The finishing details being accomplished, we still have, however, staring us in the face the worst feature as to stability—namely, that of the molecular change in the filling by the constant stress of mastication, which forces the foil to the periphery of the cavity, and ultimately causes the fracture of one or both of the walls supporting it. This may happen within a few months or within a few years, but the result is the same; the operation has to be renewed and enlarged, and as it was in the beginning, so it will be in the end. Now, how are we to overcome this difficulty? I know of no easier or simpler method than by the insertion of a good practical inlay.

I feel that we are deeply indebted to Dr. N. S. Jenkins of Dresden, Germany, for his solution of this problem, in that he has devised a means by which zinc phosphate—which is beyond a question of doubt the most reliable filling for teeth, when properly protected—may be used with assurance of success. And while I am presenting to you a method for the protection of such fillings with gold, it is a question whether porcelain would not be just as efficacious. This is one of the problems that must be solved by the individual from practical experience, and I sincerely hope that my efforts to present this subject to you will be productive of a discussion which will go far toward its final solution.

But of one thing I am perfectly convinced, and that is, that gold foil and the mallet are things of the past and not of the future. This is the conclusion which led me to state in the beginning that I came before you with fear and trepidation; while I want to assure you that I have the courage of my convictions, and place myself on record as one of the first to accept and advocate the new art for the salvation and restoration of the teeth.

This matter has seemed of such importance that I have given a great deal of time and attention to the best possible method of producing a protection to a zinc phosphate filling, and I would present on this occasion a method which to me has proved more than satisfactory. If you can offer any suggestion for its betterment I shall feel that I have been more than repaid for my small efforts in bringing this subject before you. The following is a detailed description of my methods of making gold inlays:

I have found that platinoid, No. 30 to 28 gage, makes a most excellent cup or form for the retention of the impression material, after preparing the tooth with suitable draft for an impression and the proper setting of an inlay. The platinoid can be easily cut to shape with an ordinary pair of scissors, and bent so as to conform to the contour of the particular requirements. The "Perfection" compound is used, as manufactured by the Detroit Mfg. Co. It is first rolled into pencil or stick form, which permits of cutting after slight warming. The platinoid having been cut and bent, it should be heated in the alcohol flame, so that the required amount of the compound can be made to adhere perfectly to its surface, so that when withdrawing the impression the two will come away together.

In cases that have been protected by the rubber dam—the cavity of course having been prepared with suitable draft and coated with vaselin—the cup and compound may be removed without the slightest danger of any distortion.

Having secured an accurate impression in this way, it is invested in plaster, the

surfaces of which are exposed, that amalgam may be packed and burnished into the mold, resulting in a practically perfect reproduction of the cavity. The amalgam should be mixed thin, and the mercury worked out as you are filling in the mold, and allowed to stand over night. This amalgam die is taken out of the plaster and embedded in a composition called "dental lac," contained in one of the cups which belong to the Brewster so-called water-press.

Now adjust a piece of pure gold of No. 34 gage over the die, press it down into the cavity with a piece of spunk, and burnish. Take it out, trim and anneal it, and replace on the amalgam die. Put a piece of spunk in the center, place in the press and swage, and trim to about 1 mm. of the cavity margin; then anneal and swage again.

Fill the matrix with any quick-setting cement. I have a quantity of Archite cement left over, and I think probably there are others who have some also. It sets and hardens quickly. (By the way, that is the only purpose for which Archite has any value, so far as I know.) After filling the matrix with cement, place it in the cavity and instruct the patient to bite while the cement is still soft. Take it out and trim to contour, and around the edge trim below the enamel margin to about the thickness of the piece of gold that you are to swage for the top cap. Replace it on the amalgam die and swage the top piece of No. 36 gage pure gold; trim away to the line where you are to unite the two pieces, anneal, and re-swage.

I separate the two pieces, and usually find upon tapping the matrix that the cement will drop out very readily; if not, catch the matrix with the foil-carriers, and tap them once or twice. The cement will drop out whole, so that you may have it at any time to straighten out the cap if distorted in any manner.

I cut out of the matrix one-half or more of its center, keeping away from its margin in accordance with the shape of the cavity. In cutting this hole the matrix becomes somewhat distorted; I anneal it, replace it in the amalgam die, and burnish well to place; take out again and anneal, place the cement core in position, and re-swage; remove the cement core, and unite the two pieces over the Bunsen flame—at one point only—with 22-k. solder and a little powdered borax. Try it in the amalgam die, and see that the two pieces have a close contact all around. Then finish with 22-k. solder, and fill in with any low-karat solder, leaving enough space inside to act as an undercut in retaining the filling.

Set it in the tooth and allow the cement to harden. All that now remains to be done is to run a disk over the edges, and polish with a brush wheel.

I have found this method applicable to the deciduous as well as to the permanent teeth, and particularly advantageous in that it eliminates the long and tedious operations necessary for the introduction of gold foil. It also eliminates or relieves a child of the fatigue and discomfort of sitting an unnecessary long time with the rubber dam in position.

There are many other advantages that might be claimed for this or any of the methods of obtaining a perfect gold inlay, but these I must leave for your own deduction, only adding in conclusion that I sincerely hope you will find enough in this short paper to provoke a discussion which will bring out whatever good qualities this method may possess, as well as the advantages of the several different methods.

I beg you to accept my sincere thanks for your kind attention and courtesy, and my assurance that I much appreciate the honor of having been selected as an essayist of the Dental Society of the State of New York.

PROCEEDINGS OF SOCIETIES.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Thirty-eighth Annual Meeting.

(Continued from vol. xlviii, page 1214.)

SECOND DAY—*Morning Session.*

After some routine business had been transacted,

The next order of business was the reading of a paper entitled "The Porcelain Rod in Dentistry," by Dr. GEO. B. MITCHELL, Buffalo, N. Y.

[This paper is printed in full at page 31 of the present issue of the COSMOS.]

Discussion.

Dr. J. Q. BYRAM, Indianapolis, Ind. Dr. Mitchell has given us a very elaborate *exposé* of this subject, and I feel that his position is one that needs but little defense, yet it is one that is open to a great deal of criticism. I am always glad to admit it, when I find someone more skilful than I. Anyone who can take burs and manipulate them in cavities on the buccal surfaces of molars and bicusps, or even on the labial surfaces of the incisors and canines, and prepare them so that they are absolutely the size of the bur, I am frank to say can do more than I. I never saw a skilled machinist attempt to drill a hole without first placing the work in a lathe or similar apparatus where he would have every mechanical assistance, and it seems quite impossible that we can take burs in right-angle handpieces and drill a hole—if I may so call it—so that the diameter of that cavity in any direction will be absolutely the same as the diameter of the bur. If it were possible to do these things, I grant you that the porcelain

rod would have great value in such cavities.

Dr. Mitchell makes the claim that many times the margins are invisible. I have seen a few inlays constructed by the process of burnishing in the matrix where the margins were invisible. But they are exceptions, and I think the doctor will have to admit that it is the exception rather than the rule, where he has invisible margins by this method. One of the first criticisms would be upon the cavity preparation of this system. I am sorry that the doctor did not go into the technique of cavity preparation and tell us how to prepare the cavity represented in Fig. 31, and how he prepares the rod so that it absolutely fits that cavity. I am frank to say that I cannot do it, and it seems to me that in most cases the time consumed in such operations would be greater than that occupied in burnishing the matrix and fusing the inlay. It is not the little inlays that bother us most, because they are comparatively few. I believe in the majority of cases we do not have small cavities like those represented here, and if your patients in the East have this form of cavities you are more fortunate than we are in the West. We find that the cavity not only involves the middle third of the tooth, but extends in one or both approximal directions. If it were possible to find more of these smaller ones, this system would probably be of great value. I have discontinued preparing most small cavities in circular form, and I believe there are good reasons for it. In the first place,

a circular filling does not give the same cosmetic effect as where it is prepared in a more irregular marginal form. Another thing: Always remember that the labial surfaces of the incisors and canines, and especially the latter, are curved in both directions, the curvature being greater mesio-distally. In order that we may get the proper depth of the cavity by this method at the extreme mesial and distal edges, it is necessary to grind the porcelain so that it conforms to the shape of the cavity. If this be true, then it seems to me that more time is consumed than would have been the case in burnishing in a matrix and fusing an inlay. But the essayist very nicely gets over this by saying that, where indicated, they make ideal fillings. As he has mentioned it himself, it is hardly necessary for me to dwell further upon that point, because I believe that no sane American dentist would attempt to fill such a cavity as you see represented in the bicuspid, and consider it good practice. I question very much whether this method will do for general practice.

The essayist also speaks of colors being the same. I can hardly understand that. When we take a piece of porcelain in the shape of a cone, made of the same body, using the same pigment, we find a variation of the hue of that color dependent upon the thickness of the mass. Can we expect to take one of these rods, cut off a thin section, place it in the cavity, and then have the same color that we had originally in the rod? This porcelain is translucent just the same as other forms of porcelain, and it would seem that we have the same difficulty in obtaining color here that we have in other forms of inlays. I wish, however, to compliment the essayist, because I think it is a subject well worth bringing to our attention, and one well worth studying. I frankly admit that my experience with the porcelain rod has been limited; I have used it in a few cases, but not to the extent that the essayist has, because I am an advocate rather of the matrix system.

Dr. C. H. BARNES, Syracuse. "A place

for everything and everything in its place." If the dental profession carried out that rule to the letter, what an increase there would be in the number of perfectly satisfied patients. As each new method or material is presented to us we either take it up eagerly to the profit of the manufacturers and overdo it, push our own good judgment to one side, and "Hip, hip, hurrah!" for the new thing in every place, or else, if we have been well bitten a few times, absolutely refuse to have anything to do with it, to the detriment, perhaps, of our patients and practice. It is a matter of individual judgment as to how a cavity shall be prepared and what it shall be filled with, in order to preserve the remaining tooth-structure and make the organ useful and ornamental.

One thing that impressed me in Dr. Mitchell's paper was his illustration of the proneness of some men to use one particular method in every case, from the days of the "Royal Mineral Succedaneum"—when the best gold operations of that day, performed by the leaders in the profession, were replaced by the dental enthusiasts of those days with the simplest shrinking silver amalgam—down through the copper amalgam craze, pulp-capping, immediate root-filling, implantation, porcelain roots, pulp-mummification, great extension, and metallic root-fillings. Do you remember cataphoresis and Archite cement? Now it is inlays, gold and porcelain, Ascher's cement, and somnoform. All of these materials and methods are correct in their place, but not every place is correct for any particular one of them. It is a matter of individual judgment—the treatment and preparation of a cavity and what it shall be filled with—and this judgment is guided by the operator's ability in the use of certain methods and materials, modified by the particular fad with which he is indulging or experimenting at the time. Good judgment is a polite name for common sense or horse sense, which causes a man to do the right thing in the right way at the right time in the right place. The more common sense that is mixed with your

filling material the better; and be careful that it does not burn out when baking the porcelain. I am not deprecating the spirit which impels a man to experiment with a new material or method which some clinician has recommended to be used everywhere every time, with saving of time. He ought to try it. If there be a new method or new material, it is his duty to himself and his patients to learn all about it and use it in its place. I wish the essayist had laid more stress on the selection of cavities for porcelain-rod inlays. I have heard more than one paper on selection of filling materials, but I fail to remember one on the selection of cavities. In this age of advance in the dental profession, the man who gets the "one-filling-material-everywhere" habit ought to have a paper written for his special benefit.

I always had an idea that I could do anything that anyone else could, and I can. I have two hands, two feet, and a reasonable amount of brains, all of which have been in training for several years, so why cannot I perform the same operation that someone else does? I know I can, but I also know that in using the same materials and methods as does Brown, Smith, or Jones, I cannot do so well as they, and if a thing be not done well it is done wrong; therefore it is wrong for a man to perform an operation for a patient that he cannot do well. He should either have better training, or adopt a different method. The natural talents of different men vary not so much in kind as in degree. We all have some eye for shape, form, and color, but how much more easily and neatly will one man make a baked porcelain inlay than another! Without any difficulty he selects just the right color and shade—or knows that if he has not done so he can rectify it before the final bake—gets the contour correct, and when cemented in place his inlay looks as natural as the tooth; and he did not spend an hour grinding off the excess of porcelain, either.

Perhaps I am wandering far from the paper under discussion, but the porcelain rod must go through the same process of being weeded out of cavities not

adapted to it, as has been the case with every other filling material we use or have experimented with. There is a place for each and all of them, though the place for some is not in a dental office, much less in the mouth of a patient. I would suggest to go slowly with most of them. Let someone else have a share of the successes and failures of the newest new. The doctor has given a terse outline of the uses of the porcelain rod for making an artistic and natural restoration of a carious tooth. There is no doubt in my mind that it is better adapted than any other filling material in the case of those rarer circular labial cavities in the anterior teeth. The amount of time required is an objection—generally two sittings. A cavity of that class is the simplest in which a filling can be inserted. Suppose it be a fused porcelain filling and your color is wrong the first time, and you bake two, perhaps three, before you are satisfied; which method has consumed the least time? But if your color and contour had been right the first time, you would have saved an hour on your day's work and finished the operation at the one sitting. In, say, one-quarter and three-quarter circular cavities in the incisive edge, I can bake a more satisfactory piece of porcelain than I can grind in, and in so doing save time. Personally, I find very few cavities in which I cannot use to better advantage some method other than the porcelain rod. Now, that is just a matter of the personal equation, and goes to prove the statement which I made—that I can do anything that anyone else can, but I cannot do it as well if I undertake to use his method.

Every man's judgment, even that of the most fair-minded, is biased by his personal experience. His judgment as based on his knowledge—I use the word in its broadest meaning—being based on the varied views of many men, would be fair and impartial, but his own personal experience will carry much weight in forming his opinion. In dentistry every man must be a law unto himself. Whatever method he adopts let it be that with which he can get the best results. Methods

which appeal to him as time or energy savers he should experiment with, but conservatively, until he is assured of the validity of their claims and their adaptability to his particular manipulative ability.

Think of the pieces of bridge work you have seen in the last twenty years that were failures through bad designing or faulty construction, or that should never have been inserted at all. After all, we learn more from our failures than our successes; but one can learn just as much from the other fellow's failures, and it won't hit him half as hard. Do not understand me as being opposed to every new thing that comes along, for I am not, but I try to go a little slower than the enthusiasts. Enthusiasts are all right for the profession, we need them, but the "conservative" will have less to regret than the "radical." As Dr. Mitchell showed us, some men would use porcelain rods in every possible case—and in some not possible; so some men would use gold, or cataphoresis, or Archite cement, or pulp-mummification, in all cases.

Dentistry is advancing fast, and improving, along with wireless telegraphy and gasoline engines, but do not get so far ahead at the forks of the road that you have to whistle for the rest of the procession to catch up, and then find they have taken the other road because it is better. Make haste slowly, and you will be farther ahead in your profession and stand higher in the estimation of your patients.

Dr. A. C. RICH, Saratoga Springs. I am glad that Dr. Mitchell has had the courage of his convictions. The porcelain rod has a place in our practice. While he brings us nothing new, and makes no pretense of doing so, I feel that he should be commended for re-directing our attention to this subject. The porcelain-rod filling is originally an English method of practice. I think this a result of the fact that they manufactured a porcelain of such perfect homogeneity and coloring that its use as a filling material was practically and artistically satisfactory.

The essayist insists upon the merit

of the method, and doubtless he is right. It probably is a valuable aid in many instances, but the best operators in fused porcelain work, in contradistinction, will be found to be those who give it most attention, because they become more nearly perfect in manipulative ability or technique. Preferably, then, most operators should adhere to one method, thereby achieving greater perfection.

Perfect circles, squares, diamonds, crescents, or other geometrically shaped cavities detract from a perfect operation, because the esthetic eye is shocked by the perfectly regular substitute for lost substance—irregular lines are not so easily discerned.

The contouring of a porcelain-rod inlay after fixation may be the very means of inviting recurrence of decay, by the destruction of the fine edge of enamel. The reasons stated for the non-use of this method are potent. It is unnecessary to enlarge on the points of excellence of the method. Dr. Mitchell should have our hearty thanks for bringing again to our notice the porcelain rod in dentistry.

Dr. R. H. HOFHEINZ, Rochester. No doubt Dr. Mitchell had myself in mind when he spoke of the old gentlemen who would report some of the joyful moments they had spent in making the porcelain-rod inlay, because he saw in my office many of these fillings which I introduced some fifteen years ago, and which are doing good service today. I am quite cosmopolitan in my dentistry, but I do not see how the doctor can enumerate eighty-one different cavities—except those of different sizes—in which he places the porcelain rod. They have certainly great advantages and possibilities. Some say they can put in a porcelain inlay quicker than a porcelain rod. I do not agree with that, unless it be that they choose the wrong place for either one or the other. The porcelain rod in the small circular cavities on the anterior teeth, and particularly upon the lingual or buccal surfaces of posterior teeth, where the color problem does not enter, I think can be inserted much more quickly than any inlay which I, at least,

can make. The greatest disadvantage of the porcelain rod is its lack of variety of colors.

The essayist has laid particular stress upon the fact that the bur should at all times be held at right angles with the bottom of the cavity. That is one of the essential features in the success of the porcelain-rod inlay. If this is not done you will have such an imperfect margin that in time it must fail.

The color problem can be overcome where it is the choice of the operator to use the porcelain rod, say upon incisive labial cavities. I should recommend in this case to grind the inlay to the natural contour of the tooth before cementing. After having it ground very nearly to the contour, drop a piece of hard wax in the bottom of the cavity, insert the inlay, and shape the labial contour. The inlay is then removed, and if it be necessary to get a variety of colors, you can bake a lower-fusing body on the inlay, and get the desired variety of colors very easily.

The question of cementation has been brought up. Not long since I read a paper written by Dr. Head, in which he says that a large body of cement is always necessary to retain an inlay, and I think that the larger the body of cement in the cavity, the safer the inlay is held. For that reason, after the porcelain rod is made, I have been in the habit of making that part which enters the cavity cone-shaped, so that I get more cement in the bottom of the cavity than at the margins.

Dr. Byram has told us repeatedly that he has not seen so many of the small cavities in the West as we see in the East. I do not know why. I meet in my practice with a great many of these small labial cavities. Of course in the West they do things on a larger scale than we do in the East, and it may be that they make these cavities much larger than we do. There is no good reason why, in a tooth which may show a slight line of disintegration in the enamel labially, especially along the gum line, we should not put a small porcelain filling in the cavity proper, whether by the rod or the matrix system, and by rigid prophylactic

treatment keep the rest of that surface free from disintegration by decay. In my practice I have many of these cavities filled with porcelain, and I keep the rest of the surfaces free from decay. It may be that the doctor applies the western degree of extension, and thinks it is wiser to extend the cavity from the mesial to the distal surfaces. Whether that is best I very much doubt.

Dr. Byram has also taken exception to the method of filling these teeth with the porcelain rod. I do not know of any better one, and I will be very grateful to Dr. Byram if he will tell me of it. Invariably such cavities are extremely small, and it is in these small labial cavities where the porcelain rod is best indicated. Did I understand Dr. Byram to say that it would be bad practice to fill a tooth with the porcelain rod as illustrated in Fig. 23?

Dr. BYRAM. I would like to ask Dr. Mitchell if it is intended to show an open space? That is, is the approximal surface involved?

Dr. MITCHELL. No.

Dr. BYRAM. Then I was mistaken. It looked to me as though the hole was drilled through, and involved the approximal surface.

Dr. HOFHEINZ. I am sure you misunderstood the drawing. I think if the porcelain rod has a place at all, it is in cavities of that kind. They are better and more substantially filled by means of the rod than with anything else, because the circumferences of the cavity labially and lingually almost invariably agree, and for that reason you can use the same bur, and have the same circumference of the inlay.

Another cavity in which the porcelain rod is very much indicated is the extremely small cavity that you find on the incisal portion of those teeth suffering from faulty enamel development. These cavities are filled in my office with rods made by myself, not bought.

I think that after all is told the porcelain rod has many excellent applications; places where it can be properly put, just the same as the matrix inlay has in so many other cases.

Dr. MITCHELL (closing the discussion). I think Dr. Hofheinz has ably defended this system, and he has covered the principal additional points which I should have otherwise referred to.

I want to say in answer to Dr. Byram that I do not think I made the statement that this was an absolute method, but I said it was the most accurate of any method which we have. I do not mean by that to intimate that this system can be used everywhere. We see a great many buccal cavities on the molars and bicuspidis that can readily be made round, and most men fill these cavities with amalgam. Now, if you will use the rod inlay instead of the amalgam for such cavities, you will have over fifty per cent. of betterment of the conditions there. As I said in the paper, in its place and used properly, it is one of the most satisfactory methods which are available to us.

The subject was then passed.

A paper was then read by Dr. W. B. DILLS, Brooklyn, entitled "Gold Inlays."

[This paper is printed in full at page 40 of the present issue of the Cosmos.]

Discussion.

Dr. JOHN I. HART, New York city. I can agree with nearly everything Dr. Dills has said, with the exception that I think he is a little enthusiastic when he says the mallet and the foil in their various forms may pass out of use. I think that in the smaller cavities in the back teeth the foil and mallet will always be used, but in the large cavities involving the approximal and the occlusal surfaces of these teeth I am sure that the gold inlay saves the patient, saves the operator, and will save the teeth. We get the density, we get the contour, and we get the margin with infinitely less expenditure of time and energy than we could by malleting-in the filling and having the patient worn out nervously when we are attempting to finish that filling down. I like the type of inlay suggested by Dr. Dills much better than that suggested by Dr. Perry, in that the Dills inlay has a hollow surface on the inner side, which admits of a larger mass of the oxyphos-

phate, thus protecting the pulp from thermal changes if we are working on teeth with vital pulps; and it also gives a better hold to the inlay, owing to the hollowing out on the inner surface. Dr. Dills said that some operators might be able to place a porcelain inlay in the back of the mouth as well as a gold inlay, but I do not think that porcelain is indicated in that part of the mouth, as it is not so strong as the gold inlay.

I can confirm all that he says with regard to its advantages, and his technique of manufacture differs little from my own; and I do not think it would be well at this hour to take up the time of the audience with the technique of making the inlay. All I can say to those who may not have tried the gold inlay is, Try it as soon as you can; and I think you will place the valuation on its merits that it deserves.

Dr. W. D. TRACY, New York city. It is interesting to note the degree of enthusiasm with which Dr. Dills speaks on the subject of inlays. I think we all appreciate the fact that enthusiasm is one of the personal elements that contributes to individual success in any line of work. We also know that a certain amount of conservatism and balance are necessary in the enthusiast, to prevent him from becoming what is known as a crank. If Dr. Dills means us to infer that he has totally abandoned gold foil as a filling material, then I fear he is going to be a crank on inlays. Personally, I feel that there is a large class of cavities which I can fill with gold foil, effecting the permanent salvation of the teeth with no more discomfort to the patient and no greater loss of time than would occur by the inlay methods just suggested, and I believe I shall have a good many supporters in this theory right among the inlay workers.

Do not misunderstand me. I am an ardent inlay worker myself, using both the porcelain and gold inlays extensively, and I have to thank Dr. Dills for many little points of value in the technique of this class of work.

The method of making gold inlays which is going to be of the greatest value

to the greatest number is that method which is most effective in saving time for both patient and operator, and I think I can go Dr. Dills one better in the *modus operandi* in compound inlays in molars and bicuspid. My method is similar to his up to the point of taking the impression of the cavity. When the Perfection compound in its little metal tray has been pushed into the cavity in the tooth, it is hardened with a jet of cold water from the syringe, and left in place a few moments until a mix of plaster is made. Now, with a partial-impression tray adapted to the needs of the case, a plaster impression is taken right over the little compound impression, and the imprint of the cavity proper will come out with the plaster if the cavity has been properly prepared. A wax bite is next taken, and the patient is then allowed to go. Now pack soft amalgam or flow your improved Spence metal, using only enough to give a die suitable to swage upon later. Varnish your plaster impression and run the cast with plaster in the usual manner. When hard, separate, and you have a perfect cast showing the adjoining teeth, and in this cast—as a part of it, in fact—one has the amalgam die which is to be the working model in the construction of the gold inlay. Now, with the aid of the wax bite which was taken at the first sitting, get up your articulation. With this model and articulation the operator is enabled to construct his inlay from start to finish without trying it in the mouth at any stage, and without delay or inconvenience to the patient.

If the details of this method are carefully executed, all you have to do at the second sitting is to cement your inlay and burnish the edges. Please note that there is no guesswork when making inlays by this method, and that the results are more accurate than those obtained by any plan yet suggested for use in the entire absence of the patient.

Dr. H. C. FERRIS, Brooklyn. With reference to taking the bite, I believe that more operators fail on the occlusion from the manner in which the bite is taken than from any other cause.

Many dentists take the bite in wax, and rely on that entirely for the occlusion. We cannot be too careful in that particular. I take an impression in plaster of the lower jaw if the inlay is to be in the upper, and *vice versa*. I also take an impression of the upper in compound, and then use the casts from these two impressions on the bite to articulate the case, and I have been able to get very much better results. That is to my mind one of the vital points in this method.

Dr. R. H. HOFHEINZ, Rochester. Some seven or eight years ago I read a paper on gold inlays. That paper had reference only to inlays on the buccal and labial cavities, particularly where the cement had washed out in hyperacid mouths and gutta-percha was substituted. In that instance I recommended the soldering into the center of those inlays of small metallic pins, pins coming from porcelain teeth. Whether the inlays of Dr. Dills—not being entirely solid—will stand the stress of mastication is a question, to my mind. The pins soldered in as referred to will give you additional strength, and I would certainly recommend these pins, which have proved so serviceable to me in the gold inlays I have spoken of.

Dr. CHAS. F. ASH, Brooklyn. There is one point that I would like to speak of in reference to gold inlays. In the large approximal and occlusal cavities, and in compound cavities in general, I follow the same line of practice as the essayist, but there is a very easy method of putting in gold inlays on occlusal surfaces that has not been mentioned. After preparing the cavity, taking the impression in compound, I fill the impression with Archite cement, which sets very quickly, as you all know. You can separate the impression and the cement very soon. Place a die so made into the swaging press and with a little piece of gold upon it swage a matrix, putting it back into the cavity for a little final burnishing, and then fill your matrix with 22-k. solder or plate. The whole is then put back into the cavity, the edges polished, and the inlay set. The entire operation can be done in about fifteen minutes.

Dr. DILLS (closing the discussion). Dr. Hart spoke of the use of the gold foil in the lower teeth. I would say that I think I have a better filling with a combination of cement and porcelain or cement and gold than you have with cohesive gold.

Dr. Tracy thinks I am enthusiastic in regard to this system. I beg to differ with him. I put gold fillings in once in a while, but for years I have inserted very few. I know I took a very strong stand; I expected to be more severely criticized than I have been; I want to thank the gentlemen for being so lenient. I think Dr. Tracy's method ~~some that~~ simplifies the making of the inlay, because it can be turned over to one's mechanical man.

With reference to Dr. Ash's method, I think there are different methods that are of value. Sometimes, where I have a deep occlusal cavity, I fill in the inlay with 22-k. solder without stopping to swage up a cap.

The Committee on Practice, Dr. E. HOWARD BABCOCK, then read the following report:

REPORT OF COMMITTEE ON PRACTICE.

As I understand it, the Committee on Practice is expected to submit a report covering new appliances, methods of operation, additions to the dental materia medica, or such other subjects as may be deemed of general interest.

When I began to look over the current dental literature, I found in the December issue of the *Items of Interest* an article entitled, "A *Résumé* of the Later Appliances and Materials Used in the Practice of Dentistry." It was the report of Dr. B. F. Gray of Colorado Springs, made to the Colorado State Dental Association. As this report is so complete and comprehensive, it would have been impossible for me to have made a report on the same general lines without covering about the same points, thus laying myself open to the charge of plagiarism. Also the same issue of the *Items* contains a report of the Materia Medica

Committee of the New Jersey State Dental Society. This report is rather full, covering the leading recent additions to our materia medica. Consequently I shall pass over the subjects treated in the above reports, and shall present for your consideration a few of the subjects that at the present time, judging from the dental literature, are uppermost in the thoughts of the profession.

Without fear of contradiction, I shall state that the question of inlays ought to head the list.

It has taken some years for us to begin to appreciate the value of porcelain in our dental work. Of course we have used the commercial porcelain tooth, and getting it so easily, with such a range in size, shape, and color to choose from, we cannot imagine how lost we would be if this supply were suddenly cut off, and we were compelled to fall back upon the old hand-block carvings that we read about in our text-books on prosthetic dentistry. But I refer more especially to the various porcelain bodies that offer such a wide range of usefulness in their application to our daily problems. Those of us who first used the old-fashioned gas furnace, appreciate the boon the electric furnace has been to us, and what a factor it has been in popularizing individual porcelain work.

I shall not enter into a discussion of the proper shaping of the cavity, excepting in the general statement that the cavity should give sufficient ease of access to enable the ready withdrawal of the matrix when formed, and also that it should be so formed that the inlay will have other support against stress and strain than that furnished by the adhesiveness of the cement alone.

Whether to use gold or platinum for the matrix is an all-absorbing question. Personally, I prefer platinum, because it retains its shape better and seldom has to be invested. I use it 1-1000 inch in thickness in the posterior part of the mouth; and 1-2000 in the anterior portion. Investment wastes time, because more time is required in the heating-up and cooling-off processes; and if there

chances to be even a very slight tear in the matrix, there is much lost time, owing to the fact that the investment rapidly takes up the moisture from the body as it is being placed in the matrix.

Gum camphor combined with paraffin seems to make the best material for packing the matrix before removing it from the cavity. Use the paraffin first, following it with pieces of gum camphor crowded in upon it. The paraffin is more adhesive, while the camphor gives stability. Fortunately, both can be burned away without leaving any perceptible residuum.

The lower-fusing bodies seem to allure men on to try their hand at porcelain work; but the more advanced operator, appreciating the necessity of retaining both color and form under the repeated applications of heat, is very apt to adopt the higher-fusing bodies. This will become more and more the case as the price of a reliable pyrometer is brought to such a point that the average practitioner shall feel he can afford to own one.

Porcelain inlays should be grooved by the use of small diamond disks, and then, after imbedding the outer surface in beeswax, hydrofluoric acid should be used to remove the glaze from the portion that has been left exposed to its action.

Gold inlays are of great value as time- and labor-savers in posterior teeth with frail walls. But where the walls are strong and all parts of the cavity are reasonably accessible, a well-condensed gold filling will still be superior to each and all of its latest rivals. Given a properly shaped cavity and a well-made inlay, the lasting qualities of the entire work will depend entirely upon the cement used for the setting. Only a good hydraulic cement should be used, and preferably a quick-setter.

"A Microscopic Study of Cements," by Dr. Geo. C. Poundstone, of Chicago, read before the Illinois State Dental Society, May 10, 1904, appears in the *Dental Digest* for January 1905.* This article may have been overlooked

by many of our members, and I wish by this reference to bring it to their attention. The author endeavors to show that in the case of some cements the particles of the powder are so coarse that it would be impossible to bring the inlay into the close contact necessary for perfect work. In some cases, these particles seemed to fill about the same office that the broken stone does in the modern concrete construction—it acts largely as a binder. Gas or air bubbles are developed during the process of hardening, and seem to make the cement porous, thus inviting the ingress of the fluids of the mouth, causing disintegration. It was shown also that most of the cements tested continued to expand for at least twenty-four hours after mixing. This might account for some of the differences of apparent adaptation when seen several days after the original insertion.

The above article is interesting and valuable, as it presents another method for the investigation of the physical properties of cements.

Ascher's "artificial enamel" is one of the latest claimants for attention. The manufacturers state that it will make a permanent filling. It mixes with a sort of granular "feel," is a slow-setter, and must be protected from all moisture for at least twenty minutes after placing it in the cavity. It finishes off very nicely, resembling porcelain. A fellow dental practitioner was so enthusiastic after using it, that he said it would entirely supersede the porcelain inlay. Until we have a longer acquaintance with its properties and lasting qualities, I should advise against its use for setting inlays.

In the making of all inlays, where the cavity is approximal, full restoration of contour is difficult to attain; but it should be accomplished, as lack of such contour is a great injustice to the patient, and will often cause serious trouble owing to recession of the gums.

Before leaving the subject of inlays, I wish to bring to your attention some

*See also Dr. Poundstone's paper read at the Fourth International Dental Congress, at

St. Louis, Mo., August 31, 1904, entitled "The Cement Problem in Inlay Work," *Cosmos*, 1905, vol. xlvii, pp. 756-778.

small rubber wheels—Dr. Jenkins' porcelain-polishers. They should be mounted on a screw mandrel, and kept wet while in use. These little wheels will restore the gloss to a porcelain inlay after it has been ground for close surface approximation at the cavity edges. The manufacturers could improve these polishers by making them a trifle harder.

The advent of the inlay, as well as that of the latest produce of the cement manufacturer, brings up afresh the oft raised but never settled question of "fees."

In the May 1905 issue of the *Items* appears a paper by Dr. Robert H. M. Dawbarn, New York, on "Professional Fees and Fee Bills." The *Dentist's Magazine* for April 1906, quoting from the *Dental Brief*, gives an article by Dr. F. L. Fossume, entitled "High Standards and Financial Success." Both of these articles are worthy of a second perusal. While the question of fees is influenced very largely by local conditions, still there must be some basic principles governing the correct solution of the problem, and there can be no better time or place to attempt to discover them than at this state meeting.

As stated before, the inlay, because of the nice degree of skill and artistic taste required, together with the amount of time consumed, seems to call for an increase in the amount of the fee. And yet, on the other hand, as the durability of the inlay depends very largely upon the lasting qualities (non-solubility in the saliva) of the cement used for its fixation in the tooth-cavity—and, as we all know, the durability of any known make of cement is an unknown quantity—how much more should the patient be charged for the inlay in comparison with the charge that would be considered right and proper in the case of a reasonably difficult gold filling?

Likewise, in the case of some of the newer cements: They cost more at the very start than do many of the older cements; they take more care to manipulate, as well as time in the setting and finishing; and their manufacturers claim that they make permanent fillings. Shall the patient be charged proportionately

to the time consumed, or shall the question of lack of permanence be taken into consideration as an argument against the increased fee?

Should fees in all cases of similar work be made similar in amount, or should the punishment be made to fit the criminal?

A free discussion of some of the above points will prove of value to the younger members of the profession, saying nothing of the benefit that must of necessity accrue to many of the older members.

Such a discussion would confirm the wisdom of having a sort of "free lance" among your essayists.

Respectfully submitted,

E. HOWARD BABCOCK,
Committee on Practice.

Discussion.

Dr. M. L. RHEIN, New York city. I think the society has been fortunate in listening to the report by Dr. Babcock, which, so far as the subjects discussed are concerned, is more conservative than some of the other papers we have listened to during this session on this same subject. In the main I am thoroughly in accord with the sentiments of our committee on this matter, and I think that the profession at the present time is in danger to a very large extent by reason of the inlay craze—if I may call it such, for it has become a craze; and I do not care what fad there is that rises in professional practice, how great the method may be, or how much it may be needed, the tendency to run wild over it ought always to be more or less guarded against. We have listened during this meeting to papers—we have listened to one this morning—on inlays, that spoke of the disappearance of the gold filling, of their entire abandonment. I have read such remarks of practitioners for some years past in discussing this inlay question, and the tendency of remarks of this kind upon men who have been in practice for years has very little bad effect—it does not do any harm; but the tendency of such extreme remarks upon the young men just entering practice I consider

most damaging, most detrimental to their future interests; and I cannot conceive of any greater duty that presents itself to the older practitioners than to strongly condemn the tendency to go to extremes on this inlay question.

Now, if we stop to think for a moment, the porcelain inlay has only had a comparatively short time of trial in regard to its prominence—I mean the porcelain inlay in its present state of perfection; and the gold inlay in its present state of perfection has had a still shorter period of trial so far as permanence is concerned. For my part, I have seen failures of permanence in porcelain fillings that were beautiful when inserted, and this only strengthens me in the position I take. Not that this work is not the most approved method of operative dentistry in selected cases, and one that should be encouraged, but I disapprove of these extreme assertions that the gold plugger and the gold foil will disappear from our cabinet case, and that we will have no further use for them. And if this point of criticism be true of the porcelain inlay from the standpoint of clinical experience, it is much more so in regard to the gold inlay, for the gold inlay is much inferior to the porcelain inlay as a tooth-preserver. I do not speak of it from the point of strength in regard to standing stress under occlusion, but I do speak of it in its peculiar inadaptability in certain mouths. There is no question that the porcelain inlay well inserted seems to possess in a large number of mouths a peculiar property of preventing recurrence of caries around the margins. Now, we do not know definitely at the present time what this property consists of, but we know from very careful clinical experience that it is not present in all cases, just the same as we know that all mouths are not immune to recurrence of caries. Careful observation in the limited time since gold inlays have become popular has convinced me that the gold inlay does not possess this property in the same degree, and there are many various theories why this should be so. The character of the ce-

ment that is used in such inlays, and its combination with the metal of the baser metals that form the alloy used for soldering, point to the possibility of an electrical action around the gold inlays, a point which I wish to draw out for your consideration.

This is not intended to belittle the value of the gold inlay; I use gold inlays almost every day, but I believe there is a place in operative dentistry for porcelain inlays, for gold inlays, and for gold fillings. I want to make clear just one point that I consider valuable for gold inlays. The gold inlay is especially valuable in such distal, or for that matter mesial, approximal, and occlusal cavities, in the posterior portion of the mouth where the teeth have lost their absolutely perpendicular position, and there is such a slant to the tooth that it makes the insertion of a gold filling a very difficult operation—I do not propose to say an impossible operation, for I have never seen a case that could not be properly filled with a gold filling, but it makes the insertion of a perfect gold filling so difficult that it is a dangerous expedient. In these places the gold inlay answers a most admirable purpose, and is certainly to be favored, but when it comes to cavities that are readily accessible to any good operator—who ought to be able to place a perfectly inserted solid gold filling in the time that a gold inlay can be made and inserted—the gold filling is preferable. And what is the comparative difference? A gold filling properly inserted in such a cavity, with a lining of cement to protect the dentin and of gold in covering the enamel margins, is infinitely more perfect. The gold protects those margins much better than a cement margin, that is bound to be more or less defective as time goes on, and it is subject to those chemical actions of the fluids of the mouth that we are investigating at the present day. And I therefore say to the young men who are starting in dentistry, Beware of any advice that would foster in your minds any idea not to perfect yourself in the methods of inserting a perfect gold fill-

ing. In this I am simply seconding the admirable advice that Dr. Babcock lays down in his report.

Personally, in the use of porcelain inlays I differ with the author in regard to the form of porcelain that he uses. Originally, I for years preferred the high-fusing porcelain for inlays. The principle of inserting the porcelain inlay and the gold inlay should be to restore the missing portion of the tooth just as perfectly as we have been able to do it with gold. I have read only recently of some well-known writer having stated that we cannot always restore the contour properly, and I claim that if the inlay is inserted without the proper contour—if it does not fully restore the proper contact point, it is more defective than an imperfect filling would be in the same place, and I also claim that there is no excuse for the use of the inlay unless that contour is perfectly restored. For the restoration of that contour I believe that the low-fusing bodies are infinitely superior, for the reason that it is almost impossible to restore the missing tooth-structure with absolute accuracy with high-fusing body; whereas the low-fusing bodies can be polished and finished to proper shape in the same way as an ordinary gold filling.

I also differ with the essayist as to the value of the pyrometer. The pyrometer is indispensable in the correct baking of the porcelain filling. We have reached the stage in porcelain work where there is no valid excuse for any man to attempt porcelain work and depend upon his eye for the possible correct fusing of his porcelain, because with the pyrometer there is a certainty of results in the baking of the porcelain that it is impossible to reach otherwise; for if the porcelain be overbaked you have a material that is more or less worthless, and if it be underbaked we have the same result.

I agree with the essayist's remarks on cements in general. I believe that the coarse granular cement should never be used for setting an inlay of any character. The thinner the mesh of the cement the more positive are we that there will be less danger from the expansion of that

cement during the hardening process; and if a cement cannot be obtained that absolutely matches the shade of the porcelain, then the dead white cement is the color to be used. No attempt should be made to use a dark cement because we have a dark inlay, for if we cannot match that inlay, the dead white cement is the one that will interfere with the color scheme less than any other we can use.

One other point brought out by the essayist I would like to speak of, and that is the question of fees. As a rule, I believe that the dentists today in the city of New York are very much underpaid in all their fees. As residents of large cities we certainly realize the advance in the cost of living expenses in general from what they were when I entered the practice of dentistry, twenty-five years ago. I believe it costs in the city of New York twice as much to live today as it did at that time, and I have no doubt that in the interior the same increase in expenses meets the practitioner. Have the rates of dental service increased in proportion? From my observations around the larger cities, and from my talks with the older practitioners, I do not believe they have, and that is the basis for the statement that I make that I believe that dentists as a rule are underpaid. Now, we cannot adopt any method of graduating prices for operations or professional services; that will always be impossible. The value of each man's professional services rests right between what he believes it to be worth and what his patients are willing to pay for it. The only reason I have for referring to this part of the report of the Committee on Practice is that I believe the older men, the men who have been in practice for years, who have well-established practices, practices in which they can get the fees that they ask for, are remiss to themselves; they are remiss to their families when they continue to charge fees on the basis they charged years ago. I believe the successful older men should charge higher fees. I believe they are entitled to them, and it would make it much easier for the younger men if they followed that course.

Dr. W. S. ROSE, Schenectady. I want to commend the report of the Committee on Practice, as I think it is well prepared and well submitted. It is certainly a case of *multum in parvo*, and I think the doctrines therein promulgated are generally correct. There are some things in the report that I think it would be profitable to discuss if we had sufficient time.

The essayist's reference to porcelain inlays is somewhat conflicting. The old question of high- and low-fusing bodies is once more revived, and the committee makes the statement that the low-fusing seems to be better adapted for beginners, but in proportion as a man becomes expert he will resort to the high-fusing bodies. In addition to that he speaks of the perplexing question of whether gold or platinum should be used in the making of inlays. If the question be as to whether gold or platinum is to be used, then I think the perplexing question is still the choice between the high- and low-fusing bodies. The essayist prefers platinum because it does not require investing, and saves time. This means that he is a disciple of the low-fusing bodies, otherwise gold would not be excluded from choice, but from necessity. I surmise, however, that the dental supply houses would report much larger sales of the low-fusing bodies.

Dr. BLACK, from his statement concerning the porcelain inlay—if I could read between the lines yesterday—is under the impression that porcelain inlays at no distant date will not be so much in demand as they are at the present time. I should like to hear him commit himself a little more definitely in that line. I should like to hear more concerning the Ascher artificial enamel. And right in this connection might be considered the complex question of fees; whether the man who uses artificial enamel should charge the same as the man who makes a porcelain filling or a gold filling; that is, whether the material should enter into the question of fees.

I think, however, that the question of inlays is not the leading question before the profession today. I think there are other questions, and some were touched

on by the president in his address, that are more interesting and important than the question of porcelain inlays. I think the question of specialization in dentistry should occupy our attention; not that it will affect it so much today, but because the future of dentistry is controlled by those who are practicing now. If we encourage specialization in dentistry, we shall doubtless, by so doing, render our patients better service.

I think also there is another question that is very important to us, and that is the question of advertising the prices of dental work, the commercializing of dentistry. I do not refer to people shopping around among dentists to ascertain prices for comparison. This is a minor result, and bad; but the public get the idea from dental advertisements that a bridge is required here, a crown or an inlay there, and instead of coming to us for professional services, come with a commercial order for what they, rather than we, decide they need. The proper order is reversed; they become the judges, and we become the recipients of directions—an inferior position. I think that dentistry will occupy a lower position than it warrants among the professions until we overcome this difficulty. I saw a clipping from a paper not long ago in which were the advertisements of two dentists, and under these a half-dozen cards of lawyers. While the dental advertisements did not contain prices for work, they referred to the operators' qualifications and modern equipments. But the lawyers' cards simply gave their places of business. I have been told that in the legal profession they would not tolerate a thing like that. And it seems to me that it would be profitable if our society were to spend several sessions in carefully discussing ways and means of preventing it. If we could prevent it, our profession would immediately rise in the estimation of the public, and we would have no difficulty in obtaining fees proportionate to our services.

Dr. BABCOCK (closing the discussion). In giving such a report as this it is only natural that individual ideas and opinions should predominate, especially when

the report must be presented in brief form in order to canvass the whole territory. I feel toward all these new methods and improvements that we should welcome them. I do not consider that any one of them should run away with us, and for that reason I was conservative. I appreciate the criticism of Dr. Rhein, and also the remarks of Dr. Rose. Of course, in the question of using gold or platinum it is a matter of using the low- or high-fusing bodies. I simply advanced the idea that the man who used gold for the matrix would be compelled to make investments, and that I consider a waste of time. There are arguments in favor of both forms of porcelain, and I simply wanted to impress the idea that we should take a middle ground on such questions. These questions of methods and improvements, when first introduced, are very much like the starting of the pendulum of a clock; at first it swings off in one direction, and then back in the other, until it finally strikes a happy medium. And in closing my remarks I would make use of that familiar quotation from Pope:

In words, as fashions, the same rule will hold,
Alike fantastic if too new or old:
Be not the first by whom the new are tried,
Nor yet the last to lay the old aside.

CLINICS.

Dr. W. A. BURNS, St. Thomas, Canada.
"Quick Method of Repairing Porcelain Facings in the Mouth."

The following is a description of the technique of Dr. Burns' method: (1) Remove the remains of the old facings and pins. (2) Select a suitable facing, cut pinholes in the backing, and grind the facing to fit the backing accurately. (3) Remove the facing, take a thin strip of platinum, and bend it around the pins to form a tube by means of a pair of flat pliers. (4) Cut off the pins close to the tooth, adjust the platinum tubes, and solder each tube either by means of the blowpipe after investing the piece, or in a porcelain furnace, using the smallest possible quantity of solder. (5) Slightly enlarge and countersink the holes in the

backing; readjust the facing; hold it in position and burnish out the tube to fill the countersunk holes with a round burnisher. Then fill the opening with either gold or amalgam. The chief advantage of this method is in the ease with which facings are replaced in almost inaccessible places in the mouth, and in that it permits of the use of saddle-back teeth so suitable for obtaining artistic effects.

Dr. H. H. TOMPKINS, Utica. "Practical Novelties in Porcelain."

This clinic consisted of a demonstration of some of the changes that can be made by the operator himself in porcelain crowns and facings as they come from the manufacturer, and adapting them to special cases.

Each sample that was shown was accompanied by the original duplicate tooth so that the various changes could be easily contrasted.

(1) The clinician showed an S. S. White detachable crown in which the gum lap had been considerably extended. It was intended to meet the requirements of cases in which the gum is deeply festooned and in which the root of the tooth to be crowned cannot be covered by the artificial crown as regularly made.

(2) A Johnson & Lund diatoric tooth for bridge work; the body was extended to fill a space that was too broad for one tooth and not broad enough for two. The entire external surface of the tooth was removed and reproduced in deeper shades of the same colors.

(3) A Consolidated tooth from which the entire external surface had been ground off and reproduced, changing the crown portion from a light straw color to a deep blue, and the neck of the tooth to a color imitating that of tobacco stain.

(4) Gum effect produced on Brewster replaceable dummy tooth.

(5) That of a facing to which porcelain had been added, and which in cooling had checked badly between the pins, demonstrating the advisability of grinding out the pins when a facing is to be employed in building up an all-porcelain crown.

(6) A portion of gum enamel had

been cut from a gum section for vulcanite and spliced on to the neck of a detachable crown. It was intended to be used as a dummy on a bridge where the natural tooth had been lost from extensive recession of the gums. The colors were so harmoniously blended, and the porcelain so nicely laid on and fused, that it was practically impossible to detect the point of union on any of the samples.

Dr. F. R. WATSON, Georgetown, Canada. "Filling Lower Cervical Cavities with Gold Without Rubber Dam."

Much pain to the patient and trouble to the operator may be avoided and time saved, by laying aside the rubber dam and following this simple method with many of these cavities, and especially with the more sensitive of them. The chair should be at an angle of forty-five degrees, or nearly so. Saturate a small pledget of cotton with adrenalin chlorid solution, and apply it to the gum in the region of the cavity, pressing the gum margin down firmly if necessary. The cavity may be prepared before or after applying the adrenalin chlorid solution according to its position or sensitiveness. Now pack the cavity with cotton, and prepare the gold (softer forms preferable) and finishing instruments. Reapply the adrenalin solution to the gums, leaving the saturated pledget under the gums if necessary, and apply cotton rolls to the labial and lingual surfaces. Dry the cavity with warm air and proceed with the filling. There will be ample time to fill and polish perfectly. If the flow of saliva is copious, atropin sulfate may be administered to the patient an hour previous to the operation.

Dr. W. S. ROSE, Schenectady. "Reinforced Porcelain-face Shell Crown."

Construct a two-piece shell crown of 23-karat gold, using any good flux to fuse the parts together. As no solder is employed, this gives practically a seamless shell. Reinforce the cusps of the shell, or of an Evans crown, with pieces of 22-karat plate. Saw out the face, leaving a point of attachment near the cervix. Depress this piece for a backing, and

bake a facing of Jenkins porcelain. The prosthetic body may be used if desired.

Dr. W. C. TROTTER, Toronto, Canada. "An Easy and Inexpensive Method of Making an Accurately Fitting Metal Plate, Showing Very Little Vulcanite."

From a plaster or modeling composition impression of the mouth, make a metal die by pouring with low-fusing alloy (Olivian preferred). On this die quickly swage up a thin piece of gold or aluminum in the Olivian swager, leaving the margins of the plate extended sufficiently beyond the plate line to enable one to fit in a piece of wire around this line, and fold the margin of the metal over it in such a way as to leave jagged attachments here and there for the vulcanite. This gives a beautifully finished margin to the plate, and at the same time provides a ready and strong attachment for the vulcanite, either with gold or aluminum. Now set up the teeth with wax in the ordinary way, and invest the plate in the lower half of the flask. Carefully remove the teeth from the wax so as not to disturb the holes in which they are seated, and then with a ball of soft plaster take an impression of the buccal surface of the plate, including the inside or lingual margins of the wax. Around this plaster impression tightly wrap a piece of stiff paper, and pour the fusible metal; place in the swager and strike up another piece of thin gold or aluminum which will accurately cover the whole buccal concavity of the plate, fitting in so closely under the projecting lingual edges of the teeth as to show absolutely no vulcanite whatsoever, and also so as to hold it firmly in its place. This palatal piece of metal is now stuck down closely to the metal plate with an almost invisible layer of wax, the teeth are set back in their places, and the case is vulcanized and completed as in the usual way.

I claim for this plate considerable strength, cleanliness, smooth and closely fitting comfortable margins, and great accuracy and closeness of fit in general, owing to the extreme ease with which this thin metal can be driven into the smallest

depression or undercut. The combined thickness of the two layers is not greater than that of the ordinary heavy aluminum or gold plates used in making metal plates. The thin metal is relatively cheap, even using the double layer, as the buccal layer is usually comparatively small.

Dr. G. A. ENGLERT, Catskill. "Anesthetization of the Dental Pulp in the Presence of Pulp-Nodules and Other Obstinate Conditions."

As a rule the most extreme tenderness of the dental pulp is at or nearest the point of the lesion. Having attempted once or twice first to fully open, and secondly to anesthetize the pulp at the point of the lesion, but having failed, I then approached the pulp from another flank, *i.e.* drilling through the enamel and dentin with a double-bevel sharpened No. 1 rose bur. This procedure is less painful than would at first be supposed. Having reached the pulp at such a point, the medicinal preparation is readily absorbed, and the pressure that may be exerted is less painful. One slight application of pressure is often sufficient to enable one to return to the original cavity, which only a moment ago was almost too painful to approach, and to open it painlessly. The medicinal preparation I use is pure cocain hydrochlorid, crushed and made into a paste by the addition of oil of cloves. This is applied on the pulp, and is followed with cotton saturated with extract of Indian hemp, and the whole is placed under a compress of black unvulcanized rubber. The congestion of the pulp being relieved, I carry up the root, if found necessary, a very mild solution of cocain, say of one to two per cent. strength.

In this manner you can often obtain relief in stubborn cases of pulpitis, where it is next to impossible to approach the point of the lesion, there being so much debris lying over the pulp as to make any application at that point ineffective. Tapping a tooth can often be resorted to in hyperemia of the pulp, as well as for pericementitis when induced by a gangrenous pulp.

Dr. W. B. FAHNESTOCK, Cincinnati, Ohio. "A Simple Method of Making Gum Sections with Prosthetic Porcelain for Partial Dentures and Removable Bridges."

Not infrequently we find it preferable to use porcelain gum sections in partial cases where one or more of the natural incisors have been extracted, and where considerable resorption of the alveolus has resulted. Restoration of the facial contour with a harmonious arrangement of the teeth is quite impossible in the majority of cases when stock gum sections are used, owing to their stereotyped regularity, the disproportionate sizes of the laterals, and the absence of natural tooth-contour which characterizes almost without exception this product of the tooth-manufacturer.

It is a lamentable fact that artificial teeth as a whole tend to the conventional rather than to the natural forms, to such an exaggerated degree that it is almost impossible to produce either a partial or a full artificial denture which is not noticeable as such. In the face of these difficulties we are called upon to supply artificial dentures which will not only replace the lost organs of mastication in a practical manner, but we must restore also the natural facial expression so far as the dental organs are concerned. To accomplish this successfully calls for the production of natural effects through the selection and ingenious combination of those materials at hand which will produce the most harmonious results. There is probably no class of cases which calls for greater display of art than those where several or all of the incisors have been extracted, the alveolus has receded, and the sunken lip, when retracted in laughing or speaking, is raised to or a little above the gum line. Pre-existing irregularities of the natural teeth and present dependent irregularities in the occluding teeth, when considered in relation to facial expression, call for—in the artificial teeth—a facsimile of characteristic type and arrangement of the natural teeth. Plain teeth of the proper type or mold, with porcelain and gum enamel to supply the lost alveolus and

gum tissue, will supply the peculiar needs of such cases better than will other combinations of teeth and gum substitutes; hence I will endeavor to explain a simple and practical method for making gum sections for such cases.

For example, let us suppose that the upper left central, the upper right central, and the lateral incisors have been removed. The remaining teeth show that the V-shaped arrangement, with the lateral and central lapping from the right toward the left, is characteristic. The gum is exposed when the lip is normally retracted. Obtain a hard cast, and obliterate all imperfections, so that the cast will convey the expression which you desire to bring out in the subsequent arrangement of the artificial teeth. Outline upon the cast the area to be covered by the artificial gum, and deepen this area by scraping lightly and uniformly throughout. Make the border of this deepened area defined—as though the finished block had been slightly pressed into the cast. Burnish thin platinum upon this area, and allow it to hook over the ridge for an eighth of an inch—extending it close to the teeth on either side—and trim accurately to shape. Shape the platinum so that it will lie closely upon the cast, as would be done in placing tin foil upon a cast for a vulcanite denture. Select vulcanite teeth which will most nearly approach the desired arrangement, and then if necessary—and it will be necessary—modify their form and give them character by judicious shaping with a fine abrasive wheel; polish them perfectly in the usual way before they are finally fixed in the wax upon the cast. Now place the platinum saddle upon the cast and arrange thereon the teeth, using only sufficient wax to engage the pins and extend up behind, but not over the necks of the teeth. The extreme edges of the teeth at the necks must not be covered with wax, nor must any more of the platinum saddle be covered than is necessary for securely holding the teeth in the desired position during the process of arrangement.

When the teeth are waxed in place, lift them together with the platinum saddle

from the cast; then varnish and oil the cast for about one-half an inch beyond the area covered by the platinum—on the labial surface only. Replace the teeth and saddle, being sure that they are in the exact place upon the cast, and invest their labial surfaces in plaster—including also the labial part of the saddle and the varnished area of the cast—in such a manner that when the investment has hardened, it, together with the teeth and saddle, can be readily removed from or replaced upon the cast as may be required. Next remove the investment with the teeth, etc., and boil out the wax. The platinum saddle will separate during this procedure. When all is perfectly free from wax, replace the teeth in the original position upon the cast, and hold them there with the forefinger, when the saddle, teeth, and investment will be upon the cast in the same relative positions which they occupied before they were removed; but the wax having been removed, a space will be found behind the teeth. This space, extending around the pins, must be filled with prosthetic porcelain body. This can be facilitated by repeated applications of the dry powder, followed by flooding with clear water, then jolting and teasing the wet mass into the minutest spaces. Be sure, however, that the porcelain is not allowed to remain about the pins of the teeth, and not to fill more than the interdental spaces and the space between the ridge-lap of the teeth and the platinum saddle. With a clean cloth absorb the water from time to time during the application of the porcelain, and when the space has been solidly filled remove the investment as before with the teeth and saddle, and without disturbing the saddle, which will stick to the investment by means of the fresh porcelain. Embed the reverse side in an investment made of Peck's inlay investing compound. This second investment should engage the pins of the teeth, and all other parts. In other words, the saddle and teeth should be sandwiched between the two investments, neither of which must engage the other.

After the second investment has hardened thoroughly, cut off the first invest-

ment of plaster after the method employed in removing a plaster impression from a cast. With the plaster investment removed, the case, supported by the second investment, should present the same appearance as when waxed up on the cast, excepting that porcelain body will now be seen in place of the wax. The teeth and saddle, held securely by the second investment of compound, are now ready for the application of the porcelain body which is to restore the deficiency in the alveolus and gum tissue. Add sufficient porcelain to give the required fullness, and carve it to the closest possible imitation of nature. Exercise great care that the porcelain is packed solidly, and that the material which is placed upon the labial side shall be made to unite with that which was previously placed behind the teeth from the palatal or the lingual side. This being completed, insert the case into a cold muffle of the inlay furnace, and raise the temperature gradually to a red heat. This will be sufficient to shrink and biscuit the porcelain. After cooling, the cracks caused by shrinkage must be filled with porcelain paste, and if these cracks are not large, the gum enamel may be spread upon the case and all fused to a glaze in the second firing. If, however, there are wide cracks after the first biscuit, it may be well to fill and obliterate these cracks during successive firings, before spreading on the gum enamel. After the final glaze the investment is to be removed, all feather edges ground off, the section again placed upon the cast, and the process of mounting upon a vulcanite base completed.

Gum sections made in this manner may be mounted upon vulcanite or metal saddles, and attached to the several forms of bridge abutments, after the various methods of removable-bridge construction.

The features of this method are that the thinness of the platinum used enables one to conform it to the plaster cast without the necessity of swaging it between metal dies, while the saddle and teeth are held securely without solder during the application and fusing of the porcelain.

Dr. I. J. COE, Baldwinsville. "The Use of Cement Under Gold and Amalgam Fillings."

Although soft cement has been used under amalgam for years, my experience for at least three years goes to show that we would do well to give this valuable combination a much wider range of application. I have been using more and more extensively soft cement under both gold and amalgam, and I believe the results warrant its more extended use. The benefits noted are—

(1) *Protection.* Sensitive dentin will tolerate a filling of this kind in many cases where an all-metal filling would cause undue irritation, and probably, in time, the death of the pulp. Still greater protection may be gained by first applying a disk of gutta-percha, the under surface of which has been coated with a good cavity varnish. It affords also greater mechanical protection to the enamel walls. In many cases the cement alone is sufficient to retain the filling, thus obviating the necessity of drilling undercuts which weaken the walls. Caries will progress much more slowly under a filling lined with cement, because of the perfect adaptation of the filling to the cavity walls. In filling a large cavity with gold, we may direct the blows more squarely against the floor of the cavity, thus enabling us to fill some teeth which would ordinarily prove too weak and brittle to be filled with gold. In this way, we may in many cases mechanically protect the tooth with the filling, where it would be necessary to protect the filling with the walls of the tooth if no cement were used.

(2) *Retention.* The cement alone is sufficient to retain fillings in all simple cavities, but in compound cavities including the occlusal or incisal angles, there should be secured ample retention in the usual way, being careful to allow no cement to fill the undercuts or dovetailed spaces. In many compound fillings not subject to the stress of mastication, the cement alone is sufficient.

(3) *Color.* Cement under a metal filling will greatly improve the color of transparent teeth, and we may thereby.

conserve certain portions of labial or buccal enamel walls.

(4) *Separation of teeth.* No previous, and very little immediate separation is necessary. There is no packing of gold into undercuts which are difficult to approach, and consequently one may give his undivided attention to condensation, margins, and surfaces. Very small approximal cavities, especially those approached from the lingual aspect, are much more easily and quickly filled by this method. The cement anchors the first piece of gold, so that the work may be easily accomplished with one hand, leaving the left hand free to hold the mirror.

(5) *Pain reduced.* With simple cavities especially, the decayed dentin may be lifted off with very sharp spoon excavators, causing almost no pain, even in hypersensitive teeth. Then the margins are trimmed, and the cavity is ready for the filling.

The method of procedure is as follows: Apply a thin film of cement to the whole surface of the cavity with a flat amalgam instrument of suitable size and shape. Then quickly wiping the instrument, apply with the same instrument one layer of gold, and press it firmly into the cement. After a little experience one can do this so that very little excess cement

will be squeezed out at the margins. The gold which I prefer for this work is the strip form of Watt's crystal gold, and the cement I use is Ames' special inlay cement. This cement will set in two minutes, giving just about time to thoroughly remove the cement from the margins. To avoid the powdering of the cement, be sure that it has set before condensing the gold upon it. We have now a large flat surface to work upon, and the filling is quickly and easily completed. This gold, if properly condensed with suitable pluggers, will have a smooth and more durable surface.

Any good sticky cement will do for the amalgam fillings. Apply the cement in the same manner as outlined above, and press a flat piece of amalgam squarely into the latter. Now, with a ball burnisher, wipe the amalgam against the floor and walls of the cavity, beginning at the cervix and forcing the excess cement out at the occlusal, or most accessible portion of the cavity. If the margins are easily reached by the instruments, the forcing of the amalgam into place will free the margins from cement, and there will be no appreciable amount of cement left in the cavity. It is preferable to use the gutta-percha and varnish in all cases where we desire the greatest protection from thermal changes.

CONNECTICUT STATE DENTAL ASSOCIATION.

Annual Convention, Bridgeport, Conn., April 18 and 19, 1906.

(Continued from vol. xlviii, page 1227.)

WEDNESDAY—Morning Session.

(Continued.)

Dr. Nyman's paper was then passed, and the President announced as the next order of business the reading of a paper by Dr. V. H. JACKSON, New York, N. Y., on "Orthodontia."

[For synopsis of this paper, see "A Practical Talk on Orthodontia," published in December issue of COSMOS, vol. xlviii, p. 1233.]

Discussion.

Dr. GEORGE T. BAKER, Boston, Mass. I do not think that I can discuss Dr. Jackson's paper, but I can corroborate what he has said. The testimony of a witness in court is sometimes strengthened when it is corroborated. Now, if I can say anything which will induce you to follow his teachings, I will willingly do so. He has been a great help to me, and I believe that in this work we can accomplish results with Dr. Jackson's system very much more rapidly and easily than with any other system in a great many cases. I am not wedded to any one particular treatment in operative or prosthetic dentistry, but have always held that different cases require different treatment, and I believe this same rule holds true in orthodontia. There are cases when perhaps one system is more applicable than another, and there are very many cases in which Dr. Jackson's system is the best. That has been my experience.

I heard it said in Buffalo last summer, in discussion before the National Dental Association meeting, that there was no such thing as a Jackson system. Now, I thoroughly believe there is a Jackson

system. Dr. Jackson has worked out this method—which it has taken him years to do—and when he stands on the platform and explains a thing to us which is apparently very simple, we do not perhaps realize that it is the result of many failures and years of experience on his part; but it is true. Today, in the East, there are but two systems of orthodontia in general use. There is the Angle system—so called—and there is the Jackson system. The Angle system means the use of the expansion arch and clamp bands attached to the teeth by means of screws and nuts. The expansion arch gets its power from the nuts resting in front of the tubes of the clamp bands, as well as from the spring in the arch wire itself, and the power is carried to the teeth by means of wire ligatures. In the Jackson system the ligature is done away with altogether, as it is never used, but the force is obtained wholly by the spring of the metal in direct contact with the tooth, and the spring force is the simplest we can apply to the teeth. It is direct and positive, very efficient and completely under control; and that is a great thing in its favor. Dr. Jackson has not only given us a thorough exposition of the mechanical features, but in his work he has given us an excellent classification of the etiology of all these cases, and really that is the principal thing. The mechanical feature is nothing in comparison with the etiology, for if we really know what causes an irregularity, we are in a fair way to correct it. We may take a case in point in medicine; for instance, in tuberculosis, the cause has only been recently understood, and tuberculosis is now looked upon as a disease of malnutrition, and it is often cured by attention to hygiene and dietet-

ics solely, and without the exhibition of drugs. The minute we get at the real cause of any trouble, we can remedy it, and if we study the etiology of irregularities, then we are in position to practice orthodontia successfully. Dr. Jackson has given us an excellent exposition of this feature of the subject, and it is going to be understood more and more all the time, as is beautifully shown in his treatment of the cases exhibited in the charts.

Just one other point, and that is in starting out in this work. The best way to begin is to try a simple case. If we start with a complicated case we will have a failure, and failures are very discouraging, and may cause one to give up this work altogether. If, however, we start on a simple case—for instance a case of an inlocked incisor, which is one of the simplest operations—we will probably succeed, and then we may feel like attempting a more complicated case. And so if we start gradually with Dr. Jackson's system, I believe we will have success.

Dr. ROLOF B. STANLEY, New York. I feel in discussing the merits and demerits of orthodontia appliances that differences of opinion with regard to their value are based upon our conception of what the ultimate result should be. The ultimate result covers the whole field of orthodontia, and so a discussion of what is shown here would be entirely out of the question. There are just a few things that I would like to speak of, however.

From the diagrams I would feel almost inclined to adopt Dr. Jackson's method of correcting malocclusion, were it not for the fact that I am called upon to treat the cases which come to me for greater complications than his diagrams show.

In a large majority of the cases that I have treated, expansion of the arch was called for. Furthermore, I find that the bicuspids, laterals, and centrals nearly always need rotation, and the work must be carried on together with the expansion of the arch. Dr. Jackson said that the arches are usually broad enough in the region of the molars. I do not find

such to be the case; in fact there are very few cases which do not require expansion in the molar region.

When he speaks of the cases characteristic of mouth-breathing, or the reverse condition, lower prognathism, in every instance expansion of the molar region is necessary, not only in one arch, but nearly always in both.

Now with regard to the age of the patients: I think Dr. Jackson is entirely right in commencing as soon as any trouble is in evidence. I have many patients with the same trouble that Dr. Jackson referred to, who are very young.

As to the frequency of appointments. I see my patients two or three times a week. I prefer to do that, as I would be afraid to allow them to go three or four weeks. I do not think that it is the fault of the appliance I am using, but simply because I want to follow the changes all the way through. I want to know that all the teeth are moving on the exact line that I have outlined for them.

Allusion was made to the application of wire ligatures as seen in a clinic at one of our universities, in which the patient underwent terrible torture. I think many of these patients probably would have undergone torture in any operation undertaken in the dental clinic under such conditions. Now, I think I can apply the ligatures in such a manner that they will not make the patient squirm out of the chair. I put them on patients of all ages, and try to insert them painlessly, and think I succeed. I do not find them going into fits or trying to squirm out of the chair. It is the same with this operation as with any other. there are two ways of doing it.

With reference to the equalizing bands, as Dr. Jackson calls them, in the case in which he retracted the teeth, I cannot conceive how, as he describes the application, it can do anything else than draw the lower teeth forward more than it will retract the upper. By the use of the anchor band attached to the molars and holding the arch firmly, ligated to all the teeth, the incisors included, you can produce the forward or backward

movement of the teeth in the opposite arch. If you hold the teeth in position by ligating them to the lower arch, they will hold exactly where you want them, and all the force of the elastics will be applied to the upper teeth.

With regard to the extraction of teeth, I know that Dr. Jackson deprecates such a procedure. He says in some cases it is justified, as in protrusion. I have seen a good many cases of protrusion of the upper teeth, and have seen a great many treated by their extraction, but have not seen one instance where it was justified. By the use of the intermaxillary elastics you can retract or reduce the protrusion of the upper or lower teeth without moving the molars back a fraction of an inch. That is, by expansion alone, sufficient room can be obtained to admit of retruding the anterior teeth as much as though the bicuspid had been removed. Now, I have never, in all the cases I have treated—and I know of many others treated in the same way—felt in one instance that the operator would be justified in the extraction of the bicuspid.

Mention was made of the Angle system. I suppose that simply refers to the Angle appliances. We of the Angle school dislike to hear that term used, and when one speaks of the Angle system we attempt to correct it, and try to make the person look at it in a different light. It is a wrong conception, this viewing of orthodontia merely as a study of appliances. The principle of the Angle expansion arch is not new; it is simply modified and reduced to more convenient proportions. The Angle school represents something more than mere appliances.

With regard to starting on simple cases, as alluded to by Dr. Baker, I think any case in orthodontia requires a great deal of thought and study. Take a case that is apparently very simple, which looks as if you have only a few teeth out of position in the upper arch; when you come to study it you find a great deal more than that. The mesio-distal relation of the upper and lower buccal teeth may be correct, and therefore you might

say should not be disturbed; but in the front of the mouth, if we study it from a scientific standpoint, we might find that the condition in that region, which at first seemed so simple to treat, involved the movement of all the teeth in both arches. So I think any case means that we must study it very carefully and thoroughly, especially in young children. We must consider the type presented, and the age at which the deformity began. In some instances we are justified in leaving a result, or obtaining a result, which might be termed double protrusion, because we know that later in life, as the child grows, the face will grow into and eventually balance the prominence in the region of the mouth.

I think that the system of cribs, suggested by Dr. Jackson, is a very cleanly system, and if it would meet all requirements, it would be ideal; but in my hands, and in many others, it would fall far short of accomplishing all that I deem necessary to accomplish.

Dr. E. S. GAYLORD, New Haven. I am not in any sense an orthodontist, nor have I in any degree practiced orthodontia, but I early recognized the necessity of placing the teeth in proper position and relation to each other in the jaws. I commenced years ago sending my patients to Dr. Kingsley of New York with good results, and continued to do so until he told me that he could no longer accept my patients, having a practice that was outgrowing him to the extent that he did not feel justified in taking patients from out of the city. I then sent my patients to Dr. Farrar, with the same good results, and continued sending them to him until he told me that from increasing years and practice he was unable longer to accept my patients. I then fell back on Dr. Jackson, and he has already intimated to me that my patients are becoming a burden to him; but I want to make the statement now that I am not going to accept a turn-down from him. So that what I have to say on this subject is from the standpoint of an interested spectator, and the satisfaction I have derived in the expressions of pleasure and gratification of my

patients for the past fifteen years relative to the results of the operations by Dr. Jackson. The satisfaction I have had from hearing the testimony of these patients, both young and old, is abundant compensation to me for having been instrumental in placing them in Dr. Jackson's hands. During all these years that I have been sending patients to him—I cannot enumerate them, but there have been many, and I think today Dr. Jackson has nine or ten of my patients under treatment—I have not heard a criticism upon the part of any patient as to the result obtained; it has always been absolutely satisfactory.

Dr. JACKSON (closing the discussion). I am pleased with the discussion of the paper, and with the way the gentlemen look upon my method.

In regard to the rotation of teeth at the same time they are being moved to position, we generally begin the rotation immediately; that is, we apply the necessary force to bring the tooth into correct alignment and rotate it at the same time.

This is usually done by cementing to the tooth a collar with a lug soldered on the lingual side. The lug is usually made of a short piece of plate metal, as wide or wider than the width of the tooth, and bent at an acute angle before soldering. Force is applied with a spring made to rest on the flat surface of the lug below the flange at the mesial or distal end, according to the direction the tooth is to be rotated. Force applied at the end of a lug in this manner acts as a lever for causing its rotation as it is being moved into line.

In some cases, however, as where an adjoining tooth is beginning to erupt, or where we want to include the tooth in the anchorage for moving others, we would not rotate the tooth until later, and would arrange the appliance accordingly. With my system it is different from the use of the expansion bar in obtaining anchorage. For instance, if we want to move the bicuspid outward and keep the molars firmly in position, it is sometimes difficult to get sufficient anchorage with the expansion bar, as there is danger of forcing the molars inward

while the bicuspid is being forced outward; but with my system we have the advantage of being able to use any number of teeth required for anchorage, even using some that are to be moved later, and we can determine beforehand how to construct an appliance so as not to interfere with an erupting tooth.

Dr. Stanley spoke of regulating teeth for little patients. I would like to ask how he regulates teeth for children with the system he practices, where the teeth are just erupting. When, for instance, a lateral incisor is erupting improperly in the arch, does he apply force to correct this immediately; or does he wait until the tooth is erupted sufficiently to attach to it a ligature, collar, or a clamp-band. There is an advantage in moving these teeth while erupting, as they can then be moved more easily. The process gets harder and firmer after the tooth is erupted, and more force is required for the movement. With my system we gain anchorage by spring-clasp attachments over the deciduous molars, and extend a small wire spring to guide the tooth to a correct position.

Dr. Stanley, in speaking of my system, used the term "crib." Crib does not apply to my present system. The crib method that I devised was the passing of a wire around the teeth of the arch, resting on the labial and lingual sides near the gum for anchorage. The wire on the labial and lingual sides was connected by short pieces of wire passing over the arch at the junction of the teeth, and united with solder. In some cases the ends of the main wire were left free to form springs for moving individual teeth. In other cases, for this purpose short springs were soldered to the wire on the labial or the lingual side. The system that I am describing today is entirely different. I term it the Jackson, or the "arm and finger system."

The doctor says that he sees his patients three or four times a week. I usually see my patients but once a week, and frequently have cases where six weeks intervene between visits. The appliances being removable, permit of thorough cleansing of the teeth and appliance.

The paper was passed, and the President announced as the next order of business the reading of the report of the Committee on Necrology. In the absence of the chairman, Dr. L. C. Taylor, the report was read by Dr. E. S. GAYLORD, as follows:

COMMITTEE ON NECROLOGY.

During the year passed Dr. George E. Nettleton of New Haven has been called from earthly scenes into that higher life which knows no ending. We record his departure as the loss of one who for many years has been a consistent member of this association. For more than thirty years he had been an earnest co-worker, honored and trusted by a large *clientèle*. His positive yet affable nature won for him more than usual the respect and confidence of all who knew him. He was also a warm friend and helper of many young men entering our profession.

The following resolutions are submitted:

DR. GEORGE E. NETTLETON.

Whereas, By the death of our friend and co-worker Dr. George E. Nettleton this association records the loss of one of its true and earnest members, one who, while of an extremely retiring disposition, was always on the alert in consideration of the association's welfare; and

Whereas, Our profession loses a representative member and an earnest worker, who for more than thirty years had been honored and trusted by a large *clientèle*; whose positive yet affable nature won for him in an exceptional degree the respect and confidence of his patients; he was also a warm friend and helper to many young men entering our profession. During many years' association, we never heard him speak a harsh or unkind word. His memory will always be cherished by this association, which will never cease to mourn his loss; therefore be it

RESOLVED, That we extend to the family of our departed brother our sincere sympathy in this hour of their bereavement; and be it further

RESOLVED, That these resolutions be spread upon the records of this association and a copy sent to his family.

During the past year there has been removed from our midst one in the prime of his life. Death, who it would seem should

have left him to have fulfilled what seems to us the full mission of life, has without warning removed one of our members, Dr. William H. Cahill of Hartford, graduate of the Philadelphia Dental College, about thirty-eight years of age. For several years he has been a member of this association, although not active in society work, and his death is mourned by his many friends.

DR. WILLIAM H. CAHILL.

Whereas, It is with regret that we have learned of the death of Dr. William H. Cahill of Hartford, which occurred on August 15, 1905; therefore be it

RESOLVED, That in the death of Dr. Cahill the association has lost a conscientious, kind-hearted member, and one who although not so active as some in the affairs of the association, was always in sympathy with its best interests; and be it further

RESOLVED, That these resolutions be placed on the records of the association, and that a copy be sent to his brother.

Respectfully submitted,

E. S. GAYLORD, *Chairman pro tem*.

Dr. McLEAN moved that the report of the Committee on Necrology be accepted as read.

The motion was carried.

The Committee on the President's Address was next called upon.

Dr. C. W. STRANG. In so far as the recommendation contained in the President's address regarding raising the dues is concerned, your committee has carefully considered the matter, and after due deliberation would recommend that the annual dues be increased one dollar, and so raising them to three dollars per year. I would suggest that this be presented to the society in the shape of a resolution, to be acted on finally at the next annual meeting.

Dr. G. O. McLEAN then presented the following resolution:

RESOLVED, That Article 4, Section 1, shall be changed to read: "Active members shall sign the Constitution and pay an admission fee of three dollars, and annual dues of three dollars in advance."

The report of the Nominating Committee was next in order, which report was as follows:

President—A. W. Crosby, New London.

Vice-president—F. Hindsley, Bridgeport.

Secretary—E. S. Rosenbluth, Bridgeport.

Assistant Secretary—A. V. Prentiss, New London.

Treasurer—W. O. Beecher, Waterbury.

Executive Committee—F. T. Murlless, Jr., Windsor Locks; F. W. Brown, New Haven; and F. J. Erbe, Waterbury.

Motion was made and carried that the report of the Nominating Committee be accepted, and that the secretary be instructed to cast one ballot for the entire list of nominations for the ensuing year.

Drs. Gaylord and Brown were asked to conduct the new president to the chair.

Dr. GRIFFITH, in retiring from the office of president, said:

Dr. Crosby, I am very glad to turn over to you the duties and responsibilities of the office which you are about to occupy for the coming year, trusting that the support and encouragement which has been accorded me will also be yours. Because of our faith in your ability to conduct the affairs of the association we have no hesitancy in committing those affairs to your care for the ensuing year. I congratulate you.

Dr. CROSBY, in accepting the office, said:

If I am to be fortunate enough to receive the support and encouragement accorded the retiring president, and fortunate enough to make the meeting in New London as successful as this one has been, I shall be very proud. Gentlemen, I appreciate the compliment you have paid me in electing me to this office.

Dr. McLEAN. I move that a vote of thanks be extended to the various essayists and clinicians and the retiring officers for their efforts in making the meeting a successful one. I would also like to include in that a vote of thanks to Dr. Anthony, the COSMOS reporter.

The motion was carried.

There being no further business before

the association, motion to adjourn until the next annual meeting was made and carried.

THE CLINICS.

Dr. H. E. HOSLEY, Springfield, Mass. "Method to Prevent Shrinkage in Soldering Bridge Work."

The clinician claims that the reason of a bridge binding is because of the shrinkage in soldering, and to overcome this he cuts the model, and spreads the abutments apart sufficiently to allow for such shrinkage. The space, of course, is in proportion to the size of the bridge to be made. A groove is made at the bottom of the model to insure the proper position of the abutments when the model is again fastened together.

Dr. W. B. DUNNING, New York, N. Y. "Manipulation of Non-cohesive Gold on the Wedging Principle."

The instrument used in this clinic was a sharp four-sided wedge-shaped plugger—a single joint without serrations—and the gold used was Abbey's foil No. 4. The gold was rolled by hand into the form of pellets, and packed vertically against the walls of the cavity, finishing the wedging process toward the center. A liberal surplus was worked down to a hard dense surface by alternate wedging with the instruments named and rolling by means of a finishing bur, under hand pressure. The method was recommended for small, simple cavities, in which perfect adaptation of gold to the cavity walls may be quickly and easily obtained, the resulting filling being dense and in every way serviceable.

Dr. A. J. CUTTING, Southington, Conn. "A Process of Burnishing Gold."

Dr. Cutting's method consists of using either cylinder or foil, and with smooth points of suitable shapes that will reach every part of the cavity, of rubbing or burnishing each piece to place. Anneal the gold as required and use blued instruments, made so by the application of heat. No larger piece of gold should be used than one that can be thoroughly

condensed by the pressure of the bur-nisher.

Dr. M. R. BRINKMAN, Hackensack, N. J. "A Simple Method of Replacing Broken Facings on Crowns and Bridges."

The instruments necessary for the clinician's method consist of two drills—one for the regular handpiece and one for the right angle—one die, one tap and holder, one wheel bur, and one pair of pliers.

To repair a facing proceed as follows: Cut the pins from the backing, and with a small carborundum stone slightly concave the backing so that the facing will bear firmly on the edges of the former. Select the proper tooth. Hold it carefully in the required position, and mark with a pointed instrument the exact points to be drilled in the backing. Drill the holes, slightly diverging from the center, then use the tap to cut the thread in the latter. With the wheel bur cut a groove on the palatal side of the backing, between the holes, for clinching the pins. Take the die, and cut a thread on the pins of the tooth. At this stage of the process the tooth will be ready for cementing to place. Mix the cement fairly stiff, apply to the backing, and force the facing firmly to place. Hold it in position, and with the pliers pinch the pins into the groove; allow the cement to set, and then grind the pins flush with the backing. This completes the operation.

The special point of retention which differs from those in other methods is the interlocking of the thread on the pins with the thread in the holes of the backing. Two other points of retention are the cement and the clinching of the pins, which have been in vogue for some time. By using a small inverted cone bur, and cutting out the cement on both sides of the pins, a gold or alloy filling can be inserted in the backing, although it is not absolutely necessary for the permanent retention of the facing.

GEORGE T. BAKER, Boston, Mass. (Chair clinic.) Demonstration of Use of Thymoform: (a) Permanent Root-

Fillings; (b) Disinfecting Dressing for Infected Pulp-Canals; (c) Mummifier.

The patient presented a lower right first molar, which had caused him considerable discomfort for a long time. Almost the entire crown had been lost by caries. The caries had progressed to such an extent that the floor of the pulp-chamber, as well as the sides of both the anterior and posterior canals, were perforated. The roots were mere shells. There was not enough tooth-substance left to warrant the attempt to save it. In addition, the root was the seat of a chronic alveolar abscess with fistula. The whole tooth was in such a bad condition that for the best interests of the patient the question of extracting the tooth was seriously considered. Had there been sufficient tooth-substance to warrant its salvation, the perforations of the chamber and root-canal walls could have been capped with gutta-percha, while the abscess sac on the roots and the infected periapical tissue would doubtless have yielded to proper treatment. However, the interests of the patient are paramount, and we shall not attempt to save this tooth.

It will nevertheless serve to illustrate the use of thymoform, which consists of a liquid and a powder. The former is a five per cent. solution of thymol in glycerin, while the powder is a chemical combination of thymol and formaldehyd, mixed with absolutely pure zinc oxid. The proportion of the former to the latter is approximately five per cent. This agent disinfects by the slow diffusibility of the thymoform, which, as already stated, is formaldehyd in combination with thymol.

The fluid being hygroscopic, the moisture of the canaliculi is disinfected, and the whole tooth is thus rendered aseptic.

It is interesting to note that the periapical infection has been brought about by the infectious material of the decomposing pulp gaining access to the periapical tissues through the foramen. Now, where these infectious elements have penetrated, the disinfecting formaldehyd will as surely follow. The result will be the destruction of all pathogenic germ

life, an effectual removal of the cause of inflammation; and once the cause is overcome, one may confidently expect a return to normal conditions. The conditions of pulpless teeth are so varied that good judgment must be used in all cases. No two cases are ever exactly alike. If there be a fistula present, it is well to force a mild caustic fluid through it until it appears on the gum. In the case of an upper molar or bicuspid, due care must be used not to enter the antrum, and in the case of a lower third molar one must remember that the inferior dental nerve is often in very close proximity to the apical foramina. It is proposed to fill the lower left second molar, which is badly decayed, though the pulp is not quite exposed. The anterior and posterior occlusal cavities were united into one. The soft cheesy dentin immediately over the pulp was bathed with a solution of silver nitrate, ten grains to the ounce of water. The dentin was dried, and coated with a varnish of resin and chloroform. A very thin capping of gutta-percha was introduced to guard against thermal changes, and the cavity filled with amalgam.

Dr. WALTER H. ELLIS, Buffalo, N. Y.
 "Duplication of Models" (elastic molds).

Materials. (1) One-half pound best grade French gelatin. (2) Stearin mixture (2 dwt. stearin, 1 oz. kerosene) for painting molds to prevent the gelatin from adhering to the cast. (3) Alum-water prepared by dissolving one-half pound powdered alum in one teacupful of boiling water. (4) Soapstone to be dusted on cast to preserve whiteness.

Synopsis. (1) Brush thoroughly the cast to be duplicated with powdered soap-

stone. (2) Coat the inside of the wooden case with the stearin mixture. (3) Stick the cast to hinged portion of the case by means of a pellet of gum or clay, then shut the case and clamp it. (4) Melt the gelatin in a double boiler, in the proportion of two teacupfuls of hot water to one-half pound gelatin. Stir the mass while melting it, and when thoroughly melted remove it from the fire, and cool to a degree where it feels neither hot nor cold to the finger. (5) Pour the gelatin into the case through the hole in the roof of the case; let the mass stand for seven or eight hours, preferably over night, until it has hardened. (6) Remove the mold from the case and work the cast carefully from the mold. (7) Allow the mold to stand for one-half hour to harden, and then return it to place. (8) Brush the surface of the cast with soapstone, and then with the alum-water. (9) Give the mold a light coating of stearin mixture. (10) Run the first duplicate. (11) Watch carefully, and as soon as the plaster has set, and just before the heat incident to the setting begins to be generated, remove it from the mold, as any degree of heat injures the latter. (12) Give the surface mold a dusting of soapstone, and a coating of stearin mixture previous to the running of each duplicate. About six duplicates (good ones) can be made from one mold.

Dr. P. B. McCULLOUGH, Philadelphia, Pa. "The Artificial Substitution of a Single Missing Central or Lateral Incisor." (This clinic was later made the subject of a paper read by Dr. McCullough before the New York Institute of Dental Technique, and will be found in the Transactions of that body for 1906.)

MASSACHUSETTS DENTAL SOCIETY.**Forty-second Annual Meeting.**

(Continued from vol. xlviii, page 1255.)

SECOND DAY—Morning Session.

The meeting was called to order on Thursday morning at 9 o'clock by the president, Dr. J. J. F. McLaughlin.

The first order of business for the morning session was the reading of a paper by Dr. VIDA A. LATHAM, Chicago, Ill., on "Cysts of the Oral Cavity."

[This paper was published in full in the September 1906 issue of the COSMOS, vol. xlviii, page 905.]

Discussion.

Dr. M. H. CRYER, Philadelphia. I have not the ability to properly open the discussion. The paper itself is a classic, complete in all respects, and to discuss it intelligently one should have had an opportunity of reading it previously, so that one could study the paper and the subject carefully, as the essayist has done.

I may say a few words about the glands spoken of. All three are called salivary glands, but they are quite different in their anatomy, and the secretions vary as much as to their chemistry. The parotid is purely a salivary gland; the sublingual is a mucous gland; and the submaxillary is both salivary and mucous. As these secretions differ, the character of the cysts associated with them will vary; the position of the glands and their outlets into the mouth also vary greatly. The essayist, if I remember correctly, said that we seldom have cysts of the parotid gland. The reason for that is, that the gland as a whole is situated about on a level with the outlet of the duct, and the attraction of gravity allows the fluid to go forward into the mouth. The muscular action also favors this gland; every

time the mouth is thrown open there is a pressure which remains so long as the mouth is open, which helps to force the fluid from the gland through its outlet. Cysts of these glands are usually of traumatic origin. Again, cysts in the sublingual gland are not so common as in the submaxillary, because the former is in the floor of the mouth, covered only by mucous and submucous tissue, and has numerous outlets. While the greater portion of the submaxillary gland is situated outside of the mouth under the mylo-hyoid muscle, the duct commences within the gland, passes backward to the posterior or free border of the mylo-hyoid muscle, then upward and forward above the muscle, and terminates near the frenum of the tongue. It is in the upper portion of this duct that cysts are most common; they are often spoken of as ranula. Sometimes cysts within glands, especially the submaxillary glands, are mistaken for tumors, and it is important that a true diagnosis should be made in these cases before the operation.

There is nothing further I can add to this discussion except to heartily congratulate the essayist.

Dr. M. C. SMITH, Lynn. This is a subject that I am not properly prepared to discuss. I think the essayist has gone over the ground from a pathological standpoint in a very excellent manner. I may say a few words in regard to the treatment of such cases: When we get a case where there has been a stoppage of one of the ducts of these glands, we need to "get a hurry on" for the benefit of the patient, who wants something done, and done right away. I have seen more cases, I think, of stop-

page in Steno's duct than from other glands. The first one I remember was a complete stoppage of Steno's duct due to carcinoma, and it was one of the most wicked things I ever saw, until an opening was made into the duct. I have a case in mind of a lady who, in throwing her head down, would in some way clog up the duct, and it would immediately fill up with saliva until it assumed the proportions of a good sized hen's egg; immediately upon rising the obstruction would cease to exist, and the gland would discharge its contents into the mouth.

In opening into these cysts under the tongue I always prefer to make two openings if possible, and put in a seton, so that it will be impossible for them to close up. If you cannot get two openings, be sure that you get a packing in there so that it will remain. This may have to be kept in some time, for if left out, the opening will heal up very quickly; indeed, sometimes in a few hours, and you have a filling up of the cyst. A very small packing dipped in a saturated solution of silver nitrate and put in is one of the best things that I have ever been able to use. In fact I make it a general practice to take a fine broach, wrapped with cotton and dipped into the saturated solution of silver nitrate and pack this in these small cysts, leaving the cotton in and removing the broach. That will give you a good drainage, with as little bad results as anything I have ever been able to find. You get some drainage through the place left by the broach, and the silver nitrate keeps the parts from healing.

Dr. ISADORE LETT, Boston. I have a very interesting case to present in this connection. It is a case of suspected ranula, sent me after several surgeons had looked at it and decided that it was an affection proceeding from the teeth. I decided to take out the sublingual gland, expecting that would cure the case. A swelling would rise in the mouth, and on puncturing the swelling the contents were found to be a mixture of saliva and mucus. Before operating I introduced silver nitrate, but that did no good; then I used zinc chlorid, and after

failure in that direction took out the gland. The wound was kept open with packings for three weeks, and after these were removed the condition recurred, with considerable pain along the inferior dental nerve and back of the ear. I then introduced a probe two and one-half inches in the direction of the submaxillary gland. The condition did not improve under treatment, and I decided that the submaxillary gland would have to be removed. That has been effected, yet the same condition is still present, and I cannot understand where the fault lies. I have not been able to get a microscopic section from it, because the pain would start immediately before the swelling, and in half an hour the tumor would be formed in the mouth; then, before the patient could reach my office, it would break and discharge in the mouth. About a week ago the patient told me that he cut himself with a fish-bone in that location some years ago, and that was the commencement of the trouble. However, I have not been able to make a diagnosis leading to a cure of the case. These little tumors will spread in different parts of the mouth, and the moment they break the pain is immediately relieved.

Dr. LATHAM (closing the discussion). I wish to thank the members of the society, and especially Dr. Cryer, for the kind words spoken of the paper. I only want to say in regard to the subject that the work is certainly interesting, and if I may say it, I think it behooves every dentist to be on the lookout and watch for these conditions.

The next order of business was the reading of a paper by Dr. EUGENE S. TALBOT, Chicago, Ill., on "Errors in Dental Education."

[This paper was published in full in the July 1906 issue of the *Cosmos*, vol. xlviii, page 731.]

Discussion.

Dr. EUGENE H. SMITH, Boston. When I was asked to discuss Dr. Talbot's paper on the "Errors in Dental Education" I

gladly answered, Yes. I did not realize until I read the paper that he would touch upon matters other than education; but he has seen fit to discuss not only the past and present methods of dental education, but to severely criticize much of the technical side of dentistry, that many of us consider an advance over past and cruder methods. I do not agree with him that the art of filling teeth has not progressed in the past fifty years.

It may be quite true, as he says, that the principle of cavity preparation is much the same as it was a half-century ago; but much of the technique has changed, and the treatment of the cavities after preparation is quite different. I look upon the different inlay restorations as a distinct advance in operative dentistry. They have in a great measure supplanted the large, malleted cohesive contours that were so exhausting to patient and operator, and furnished us with a remedy for caries more compatible with tooth-substance, and, as in the case of porcelain restoration, more artistic.

In the construction and adaptation of artificial dentures, the work of Bonwill, Gritman, and Cross in the field of anatomical occlusion has been a notable step in advance. Crown and bridge work, though much abused in application, has had and still has its legitimate uses. It is quite true that in normal conditions the bridging from tooth to tooth is contrary to well-known physiological laws. So are many of the surgical operations of modern surgery, yet we are justified in resorting to it in many cases. Judiciously applied and skilfully executed, crown and bridge work proves a healthful blessing to many of our patients, and delays the undesirable hour of plates.

In orthodontia within the past few years much has been accomplished. Normal occlusion and its importance have been written by Angle in letters of gold. The technique, to which many have contributed, has also been greatly improved. Errors in this branch of our work are being made, no doubt. So are errors being made in science and research. The science of today is not the science of yes-

terday, and the science of today will not be the science of tomorrow.

Our essayist stated that deans of dental schools and editors of dental journals give no credit to the research work of scientific men. I think that upon second thought he might be induced to make a few exceptions to this wholesale charge, and especially so in my case, when I assure him that the testimony of my students will bear me out when I say that his valuable work receives full credit in my classroom. I cannot believe that I am the only one who gives honor to him and his co-workers.

Heartily do I indorse, with the essayist, the saying of Emerson, that no man can learn that which he has had no preparation for learning. It has been with this in mind that the faculty of the Harvard Dental School has, to its cost in its number of students, steadily advanced the entrance requirements, and maintained a broad and severe training in the fundamentals of medicine. I am, however, at this moment inclined to believe that the college or academic graduate is frequently poorly prepared for professions that require so much technical skill as do dentistry and surgery. Certain am I that the student who contemplates entering upon our profession should, on his way to his degree in arts or science, elect in a generous way the natural sciences. He must early be taught manual training, and follow such studies as will develop his powers of observation. It is always pleasant to speculate on the possibilities of preventive medicine, and to encourage and assist the scientific investigator. The powers of the practitioner and those of the scientific investigator, however, cannot find their full development in one man. Skilled practitioners we have, and what the dental profession most needs at the present time is thoroughly trained scientific men who can devote their whole time to dental research. This can only be brought about through properly endowed dental schools. The millennium, however, is yet a long way off.

The multitude, although knowing how to live, will not lead such lives but that a

large army of practitioners will be kept busy treating disease and repairing the waste. It behooves us, then, to say a good word for the man of practice as well as for the man of science, and to provide in our dental schools such courses as will foster the scientific spirit, and at the same time produce the intelligent and skilful practitioner.

Dr. GEORGE A. BATES, Boston. I have been much interested in the paper by Dr. Talbot. His statement that dentistry has made no progress during the last thirty years, brings to my mind two incidents which occurred more than twenty years ago. I happened to be in the office of a friend in a neighboring large city, and while I was there a gentleman came in who was a practicing dentist in the same city. After some casual remarks he, in a self-congratulatory tone, said, "I have cleaned out five mouths this morning"—it was then about nine o'clock. I drew a mental picture of the gentleman's office, and seemed to see a line of patients sitting there waiting to have their mouths "cleaned out."

I have another recollection which takes me back twenty years. In this instance, a man had in his mouth a porcelain crown which had become loosened. He had come into the dental office to have it readjusted. During the operation I discovered that the crown was set on a hickory post; I also learned that the patient was obliged, every six months or so, to have the same operation performed, because caries had penetrated into the root-canal and enlarged it so that the post would no longer remain tight. At each operation it was necessary to insert a larger post until, at last, came the inevitable extraction.

I have a crown in my own mouth which is in strong contrast with the one just mentioned. This crown is anchored in the root with a platinum pin. Over the end of the root is fitted a platinum cap, through which the pin passes. The dentist who put on this crown understood the anatomy of the tooth and surrounding tissues, so he did not make the band deep enough to wound the gingival border. Over the cap is fused a porcelain

crown, the porcelain covering the cap entirely, so that no metal comes in contact with the gum tissue. It is a thing of beauty, and I trust will be a joy forever.

Some present will remember how twenty years ago most of the dentures that came under observation were of the horseshoe variety. I am sure the dentures made by the dentists of today mark the wonderful improvement in plate work which has been achieved in the past twenty, not to say thirty years, the statement of the essayist to the contrary notwithstanding.

I cannot agree with the doctor when he says that the porcelain inlay is not an advance in dentistry. It is a distinct advance that we are able to use porcelain as a tooth-filling material. The essayist says, the tooth will discolor with age and show contrast with the inlay, however nicely it may be matched. What of gold fillings from the beginning? Is not the contrast much more striking; and in the case of the inlay, does not the patient have the benefit of the time before the tooth discolors, during which he has a filling that cannot be discovered by the ordinary observer? The difficulty of finding a cement that will hold the inlay in place is a detail that will be overcome in time, and one which I think the essayist has very much overestimated.

The essayist has spoken of "a cement that will take the place of the inlay, and which will have the permanence of gold." This is a much to be desired consummation. When we have a cement that will preserve the color of the tooth and will at the same time be permanent, it will indeed be a benefaction to both patient and operator. In the meantime we can do much with the porcelain inlay, and save our patients the unpleasantness of the ghastly exhibitions of the goldsmith's art.

I want now to address myself particularly to the subject of dental education. The question raised by Dr. Talbot presents the proposition, How shall the dentist be educated? I would not undervalue the advantage of a college education, for whatever one's position in life

a college training is of great advantage, all things being equal. But unless a man be possessed of special qualifications, a college training alone will not fit him for his work in dentistry. We are educating *dentists*, and whatever may be said about higher education in dentistry, we must not lose sight of the fact that a very large part of the work that the dentist is called upon to perform is mechanical. This is a fact, whether we are willing to admit it or not.

The dental student first of all should be possessed of a good working knowledge of English, for he is to be a professional man, and must take and hold his place in society, and be able to speak and write intelligently. In his work he is constantly coming into contact with mechanical problems, therefore he needs mathematics and physics. In the course of his studies he will be called upon to know something about the processes going on in the body, which will require more or less knowledge of chemistry. Of Latin and Greek, he needs the former for roots and derivations; the latter not at all, for it is only essential for classical scholars, and it is not the business of the dental school to teach the classics. A reading knowledge of German is very desirable, since a large part of the literature of biological science is published in that language. With such an equipment the student is ready to begin his training in the dental school.

Let us suppose two men entering a dental school, one with natural literary ability and the other with natural mechanical ability. Make an equation with these two factors, each representing an equal quantity. Add a college education to your equation, and the man who has the mechanical ability will become a dentist, while the other will never make a dentist whether he possess the college education or not.

The first man, with the preliminary training already mentioned, will be just as good a dentist without as with a college education. Why waste his time acquiring an equipment in college which, while in many ways desirable, will not in any material sense increase his efficiency

in the practice of his chosen profession? I wish it to be clearly understood that I do *not* underestimate the value and desirability of a collegiate training, but I do say that it is not a *necessity* for the dentist. Men who come to the dental school are, as a rule, such as cannot afford to attend college. This is true as to time as well as of material resources. They must get to their life-work by a shorter way or choose another occupation. It would seem that we might educate our dentists by giving them just the necessary preliminary training before entering the dental school, and use the time thus gained in such teaching as will have a definite and vital relation to the work which the practice of dentistry will call upon them to perform.

As to the courses of study in the dental school, I am inclined to agree with Dr. Talbot, but too much stress has been laid upon original investigation; this, I think, is a weak point in his essay. Investigators are born, they are not made. You cannot educate a man to become an investigator, unless he have natural endowment for the work. The man who is so endowed by nature will be an investigator no matter what his occupation in life.

There seems to be much confusion among people who write for dental literature concerning the meaning of scientific investigation. This is shown by the almost endless repetitions which are constantly occurring in the dental journals. How often do we read how to treat a root-canal under varying conditions of disease. How many papers have been written on the proper method of treatment for that much-talked-about and little-understood bugbear of dentistry, pyorrhea alveolaris. How often do we read about numerous other subjects legitimate to the dentist, and yet not a single *scientific* investigation has thus far been made. These subjects have been touched upon, and every man who has thus far attacked them has done so without reference to the work of others, and has treated them as if he were the first man to give the matter attention. This is not scientific and is distinctly dishon-

est, yet neither the man who uses another's scientific property, nor he from whom it is taken, knows enough about scientific usage to understand that any wrong has been done. The very first principle of scientific investigation calls upon the investigator for a sufficiently adequate knowledge of the literature of the subject to prevent just these errors. If a biologist were to present a paper which purported to be an original investigation to any scientific journal, and it should prove to be a repetition of something already published, the paper would be at once refused, and the author would be held in suspicion by all biologists who knew the facts. And yet, in our own profession, we see this going on continually, because the publishers of the dental journals either do not know or do not care.

There are only a few investigators, for reasons already stated. Out of thousands of men engaged in the practice of medicine, how few there are who can lay claim to this distinction.

The essayist puts much emphasis upon the need of the study of the central nervous system and evolution. Of the central nervous system we know comparatively little. Indeed we are just coming to the study of this system on general principles. There are multitudes of problems which surround the subject, and I wish to cite a few of the simplest, just to show how little we know of the elementary structures of this complex system, and that there are problems that cluster around it no matter where you touch it; also to demonstrate that we are not warranted in making deductions or drawing conclusions with the present state of knowledge.

Here are a few of the simple problems: How are the spinal ventral nerves developed? Are their fibers produced by processes of single neuroblasts, or are they due to the migration of successive neuroblasts out through the limiting membrane of the primitive medullary tube? On the answer to this question is based one of the principal arguments in the controversy now in progress over the neuron theory. Take, for example, the nerve fiber; this is one of the simple ele-

ments of the nervous system. What is the origin of the neurilemma? Is it the product of the spongioblasts which go out with the migrating neuroblasts, or is it developed from the mesenchymatous tissue which surrounds the developing fiber? We know comparatively little about the nerve cell. What is the nature of the stainable substance of Nissl? Are the varicosities on the dendrites artifacts? What is the function of the fibrillæ which permeate the cytoplasm and project into neurite and dendrite? Does the nerve cell ever divide? How do its cyto- and nucleoplasm differ from those of other body cells? These are problems which have to do with the very simplest elements of this complex system. For many years the brain has been studied, and yet how very little is actually known about it. A few regions have been provisionally mapped, but the rest is more or less unknown. The great and all-important problem that concerns the nervous system is the neuron hypothesis, and this is at present in debate. Shall we give up the neuron theory, upon which all our present knowledge of the arrangement of the nervous system is based? These are some of the problems awaiting solution, and I can count on the fingers of my two hands, out of the hundreds of men in the world engaged in the branch of science that deals with the nervous system, those who are competent to attack these questions.

The essayist has spoken of the evolution of the nervous system. Evolution is a much-talked-of subject and one about which the most vague notions are entertained. What do we know about the evolution of the nervous system? Only the other day I heard a gentleman talking about the bony tissues of the mouth keeping pace with the evolution of the central nervous system, evidently not knowing that the growth and integrity of bone is a process of metabolism, and that this process is the product of the chemistry of the cell; also that it acts by chemical affinity, without special reference to the nervous system, or at least to a limited extent, and then through the involuntary nervous system, which acts independently

of the brain and spinal cord. The process is the same in the leg of a frog as in the human mouth, and the bone in one does not differ from that of the other. The subject of evolution is at present passing through a great battle which, while it does not disturb the basal propositions of the science, affects materially the matter of factors, and until some conclusions are reached in the present discussions, the least said about it the better.

There are many problems in the field of dental science awaiting answer, but they must be attacked by men who have had the training and know how to do the work. Some such men we have, one of whom is sitting here in this hall while I speak—Dr. R. R. Andrews of Cambridge, who is a pioneer of dental histology in America; J. Leon Williams of London is another; to these two men is due in great part our present knowledge of the development of enamel, while the discovery and demonstration of the *Zahnleiste* or tooth-band by Carl Röse, marks an epoch in the study of dental embryology.

Let us look for a moment at some of the problems which address themselves specially to us as dentists. I speak from my own specialty because I am most familiar with it.

First: How is dentin developed? Does the odontoblastic cell furnish the material for the development of the matrix of the dentin, or does it come from the ground substance of the connective tissue of the dentinal papilla?

Second: Is the first enamel developed from material which is locked up or stored in the meshes of the stellate reticulum of the enamel organ? What is the purpose, origin, and nature of the internal enamel membrane described by Leon Williams?

Third: What is the nature of the vital connection, if such there be, between the alveolo-dental periosteum and the dentin? How is sensation conveyed through the dentin to the pulp without the presence of nerve tissue in the dentinal fibril, or does such exist in these structures? These are a few of the many problems

which address themselves particularly to the dentist.

When Dr. Andrews, at the International Congress assembled at Chicago, read his paper describing the fibers which extend from the ameloblastic layer into the stratum intermedium, there was little or no discussion, and the reason is not far to seek.

There is plenty of opportunity for investigation in the legitimate field of dentistry. Most of the work of this nature, however, has thus far been done by people outside the profession. Many of the problems in the pathology of the mouth can more readily be solved with a more extensive knowledge of embryology. This science of development is the foundation of all branches of biology, and when dentists have a better understanding of the fundamental sciences, we shall hear less about new remedies for pyorrhea alveolaris, and more as to its probable cause: then we shall know that it is not a disease in itself, but the result of some perhaps remote systemic condition which finds expression in the mouth. When that time comes, if it ever does, our dental literature will be purged of much of the worthless material which at present mars its pages.

I disagree with Dr. Talbot in many of his propositions, but I find myself entirely in agreement with him when he says that the reason for this condition of things is that dentists will not see over the cusp of a tooth.

In closing, there are a few things I wish to emphasize: First, I wish to express my entire agreement with Dr. Smith in his statement that dentistry did not write its last word thirty years ago, and that we do have better methods of working, and that dentists do better and more skilful work today than was done thirty, fifteen, or even ten years ago. Second, that a college education is not essential for dental students. If we are to put that necessity upon them, as preliminary to their entrance into the dental school, we will empty our dental schools and will not improve the profession.

During many years of experience as a

teacher in a dental school, I have had a large number of men under personal observation, and I am sure the profession of dentistry would have been robbed of many useful members if a college education had been a necessary equipment for their entrance into the dental school.

Here in Boston, I could point out a number of men of this character who have been my students, and who occupy high places as intelligent men and good dentists; men who are not a disgrace to the profession, but by whom the profession has been made better, broader, and richer, because of their entrance into it. So I will say, let us educate our students as dentists; let us recognize that mechanics enters largely into the warp and woof of dentistry; that investigators are not made, they are born; that the man who is an investigator, if he has the groundwork which I have suggested, will be amply able to do any work or attack any problem which may come to him legitimately.

I had wished to say something about the statements made by the essayist concerning the conduct of dental school teaching, but Dr. Smith of Harvard has covered the ground so fully and so well that I forbear.

Dr. JAS. McMANUS, Hartford, Conn. You have heard from three professional educators on this subject. Dr. Talbot has covered the ground very fully and very exhaustively; Dr. Smith very pleasantly; and the last speaker has told us a great deal that we know to be true. What I want to say on the subject is this: that if the dental colleges have made any mistake in the past, it is because they have failed to impress thoroughly on the minds of the students the necessity for study, continual study, after they leave college. Good old Professor Garretson, who talked so much about the "A B C" of dentistry, and dwelt so much on principles, used to say, "It is our duty as teachers to teach you young men principles, and impress upon your minds the necessity for study after leaving college. And we are trying to teach you to study hereafter, and to know where to look for information on any subject which comes

up, for further instruction." Now, the trouble in the past has been that they have given a little bit, but not enough, of the history of the profession, and they have not impressed strongly enough the necessity for study after leaving college. If you take many of the men who have read papers for the past few years, they have come before us to read papers which many of us have read in the earlier volumes of the DENTAL COSMOS; we know that the same things have been written and talked about years ago, and yet they are brought forward as something new.

I want to say this with reference to the teaching of the past: You had last night from Professors Brown and Cryer some wonderful exhibitions, and you have had today from our good friend Dr. Talbot a very helpful paper. I can remember when all of these men were simply dentists, practicing dentists. What are they today? They are students and scientific men, and it is a great pleasure to see what Dr. Brown has done with those malformed children to make them presentable. But here is the point: He first had a good education in the dental college, and has learned to use his fingers, and knows how to operate. His dental education has made him the surgeon that he is today. And the same thing applies to Dr. Talbot and Prof. Cryer. We have had a few men in the dental profession who have been students, and have continued to be students; they are investigators, but it is hardly possible to expect this of a majority of the students. Just as the last speaker said, some men are born with certain gifts, but the majority of our students are not. I think today that the dental students will rank with the medical students in this respect. Take any class of medical students of two hundred, and I doubt if there are ten men in that number who will stand prominently before the public as great men. So the majority of our students are simply dentists. There are dentists, and there are professional men. And I never had this so forcibly impressed upon me as at this meeting of the American Medical Association. Go over to that exhibition, and you will see numerous

appliances, and many other things; you will also see several booths filled with scientific and medical books. These books are there for the medical men to examine; they are on scientific medical subjects. They are expensive, and cannot be published unless they have readers, and that means that medical men are readers. I have never seen an exhibition of dental books at a dental meeting. I see no evidence that the majority of our men are readers. They say they do not have time; after a man finishes his daily work he hardly has time to read a magazine. Talk about trade journals; they would do a lot of good if men read them, but they do not.

In closing, I do want to say that the dental schools of the past have done great work, as illustrated in that we have such men as Dr. Cryer, Dr. Brown, Dr. Talbot, and others.

Dr. TALBOT (closing the discussion). I wish to say in closing the discussion that I would use the arguments of the two principal speakers to prove my case.

There being no further business before the society, the president, Dr. McLaughlin, declared the meeting adjourned until the next annual meeting.

On Thursday night, June 7th, a banquet was tendered the members and guests of the Massachusetts Dental Society at Young's Hotel.

After the banquet was served, Dr. J. J. F. McLaughlin, toastmaster, called on several of the members and guests for speeches, after which he introduced the speaker of the evening, Prof. J. H. MONTAGHAN of Washington, D. C., who addressed the assemblage on the subject of "America a Land of Unlimited Opportunities," as follows:

AMERICA A LAND OF UNLIMITED OPPORTUNITIES.

Last year and the year before, dealing with a subject somewhat similar to the one selected for this evening, "America a Land of Unlimited Opportunities," I dealt in more or less detail with certain

facts and figures of startling suggestiveness and stupendous significance. I shall briefly run over these figures. They deal with our fabulous wealth and our marvelous powers of production. In the first place the United States is the richest country in the world. Concreted into a mathematical expression our wealth has been put at \$110,000,000,000. Such stupendous figures stagger the imagination, for they are far beyond the power of the scientist's, much less the ordinary, mind to grasp. When an Indian runs down from the woods to Washington to see the President, he makes a note of all he sees. When he goes back to the forest he tells his tribesmen that the number of the people he saw were as the stars in the sky at night; as the leaves on the trees, or as the grasses in the field. From the Indian's picturesque and graphic language, his companions get a fairly good idea of the multitudes in the eastern cities, but when I talk to you today of \$110,000,000,000 you have hardly an idea of my meaning. If, however, in order to help you to understand by a comparison, I tell you that our wealth—piled up in a little over a hundred years—is \$110,000,000,000, while the wealth of Great Britain—a nation that sent tin to the Phœnicians and gold to the Cæsars—has only \$55,000,000,000, you begin to get a better idea of what the wealth of the United States is. France, "la belle France"—land of thrift, of olive orchards, wonderful vineyards, of flowers, of the finest fabrics, from the art works of Paris to the Gobelin's tapestries and Sèvres china—has piled up in nearly twenty centuries only \$50,000,000,000; Germany, including Alsace and Lorraine, has only \$45,000,000,000; Russia, with a sixth of the globe under its scepter and a tenth of the world's people, has only \$35,000,000,000; Austria, including the Kingdoms of Hungary and Bohemia—romance lands, all of them borderlands of the East—has only \$30,000,000,000; Italy, descendant of the Romans—with its wonderful past, its cities of all its Cæsars, its Venice, Florence, Milan, Amalfi, Rome, and Naples—has only \$18,000,000,000; while Spain, that took

billions—not millions—from the Incas of Peru and the Montezumas of Mexico, is last in our list with only \$12,000,000,000. Against all these our country has \$110,000,000,000.

Last year I put our power in another way; and it is particularly of this power that I shall talk today. I told you that our producing capacity was as follows, expressed in percentages of the world's entire products: Wheat, 22; gold, 30; coal, 32; silver, 33; manufactures, 34; iron, 35; cattle, 36; steel, 38; petroleum, 50; copper, 75; corn, 84. I have to change those percentages this evening. We have long passed beyond the 32 per cent. limit in coal, beyond the 34 per cent. limit in manufactures, beyond the 35 iron and 38 steel. Today the tables tell us that our iron and steel productions are nearer 50 per cent. than they are to the old tabulation. We are now the world's greatest, if not its most wonderful manufacturer. You see I am discreet, if not wise. I say we are the world's greatest manufacturer, not its most wonderful. I take my hat off to France, Germany, and England. We produce quantities; they still stand for qualities. In saying this I hope I shall not be accused of disloyalty to my own people. The purpose of this lecture, as I take it, is the truth. If the statistician stands for anything other than the truth he is a dangerous man.

The figures, then, of our wealth and our power to produce lead us to an analysis that is as suggestive as it is interesting. Whence came the wealth and the power? God Almighty made this land the most wonderful in the world, with the possible exception of China. Why except China? Why except any country? Well, for this reason. I want to be fair; secondly, I want to point out that China is the really great opportunity, the greatest in all the wide horizon of possibilities. We produce 22 per cent. of the world's wheat. When we get ready to till our fields as they till the wheat fields of France and Germany, the yield will be 33 per cent., or even more. Our corn yield is 84 per cent.; it could be made 90. The soil of this country is

among the world's finest. Tests have shown the soil of the Mississippi, Missouri, and Arkansas valleys to be among the richest on earth. Only the soil of Egypt and a few of the valleys of Asia can compare with them. The work of the Department of Agriculture, of Luther Burbank in California—inoculating the soil so as to increase its fertility, planting Persian peach, olive, date, and other fine fruit trees in California, Arizona, Oklahoma, and New Mexico, the removal of the spines from the cacti of the same states, converting the cause of disaster into the most succulent herbage of our cattle, giving to the world seedless apples, seedless oranges, pears, peaches, plums, grapes, etc., such as the world had never looked for even in the islands of the Hesperides—show what a world of opportunities is here. Talk of opportunities! Why the alkali plains of the West—once regarded as worse than deserts, dangerous to man and beast—are beginning to blossom as blossomed once the gardens of Semiramis, or the lands lying between the Euphrates and the Tigris, the plains of Mesopotamia or Persia. Irrigating waters wend their way out of our western hills into the orchards, vineyards, and gardens of a dozen states, transforming arid wastes into blooming vistas. In them all are found the splendid opportunities offered to the farmer and the farmer's children by the scientists of this and the last century.

As has been my wont in other years, I pause here long enough to put in parenthetically, but quite apropos, the wonderful work of a great scientist of France, Pasteur. I do this for a dozen reasons—but primarily to point out the fact that for the one opportunity presented to the boy Pasteur, a hundred are offered to the boys of this country. France lives upon the fruits of her olive orchards, her vineyards, her silk-farms, and her sheepfolds. All of these were suffering, in danger of death or extinction. Pasteur, who was a chemist rather than a biologist, went to work to discover the causes of the phylloxera ravaging the vineyards. He found it; found, too, that scions taken from the Mohawk Valley of New York, from Ohio,

California, and other states of this country resisted the phylloxera. These were put in place of the old vines, and France was saved. Her wine improved, if that were possible. The great scientist scored his success number one. I am not now paying particular attention to the chronological order of his successes. The sheep of France were dying by thousands. Pasteur went into the fields, watched the sheep grazing, learned the cause of the disease and eradicated it, although in doing so he had to encounter and fight the prejudices of an ignorant peasantry. The silkworms were dying. Pasteur went into the mulberry orchards, into the incubators, watched the worms at work, traced the disease to its source, and eradicated it. The bite of a mad dog leads to the most dangerous and most deplorable of all diseases—hydrophobia. Pasteur investigated that, wiped out the danger of it and when he died was at work on the bacilli of consumption, tuberculosis, and the bubonic plague. Again I say to the young scientists of this land, to those who are willing to work, there are bacillic and bug diseases by the dozen. To mention only one of the latter—there is the boll-weevil, the wiping out of which will mean as much to southern cotton fields as did the destruction of the phylloxera to the vineyards of France. There are millions and millions of opportunities on our farms, in our gardens and our forests. Why, until the latter are on a paying basis, and until they are saved from the wantonness and waste that has been ravaging them for over a hundred years, there is an opportunity for the statesman, the scientist, and the public-spirited citizen. An army of men is needed to put our forests in the condition one will find in the forests of Europe, particularly Germany and Austria. To organize the metric system will require a constructive genius. The forests, then, are full of opportunities.

THE MINES.

The world has a large, but after all a very limited supply of its great and important if not essential factors, coal and iron. Note what I say, important if not

essential. They are not essential. The romantic story of Italy's so-called industrial and commercial decline or decadence was very largely due to the fact that Italy had no coal, while her great rival—for two or three hundred years the world's great industrial and commercial master—England had thousands of square miles. When, in 1607, England began to apply coal to the manufacture of iron, thus getting a leverage such as would have delighted the soul of Archimedes, Europe had 14,500 sq. miles of coal; of these England had 10,560. This is what put Great Britain at the head of the world and kept her there till Anno Domini 1895, or thereabouts—or, in other words, till the coal and iron deposits of this country, backed by our cotton and corn, put it in our power to wrest from her the scepter of supremacy. The Old World's mines are worn out, or are wearing out, particularly England's; ours have hardly lost their upper layers. We have 225,000 square miles of new mines; Europe, 14,500 square miles of old ones. England will exhaust her mines in two hundred or three hundred years, while ours at the present enormous rate of production of over 300,000,000 tons a year are good for 6000 years. Only China—with 225,000 square miles, as recorded by Richthofen, the great German geographer and scientist, who spent twenty-five years in China studying its mineral resources as well as its agricultural possibilities—can compare with us, and I look upon China and the vast East as our greatest opportunity. Just as soon as the canal is cut, the Pacific puts our East with all its powers and possibilities in close touch with the Far East, where opportunities will be opened up to us as fast as evils flew out of Pandora's box. Our coal, copper, iron, gold, silver, and all other mines are opening myriads of opportunities to our chemists, engineers, mine managers, and all men of brain and brawn.

It would take hours instead of an hour, or five times ten minutes, the time usually taken for a talk of this kind, to do more than give you the outlines of the opportunities offered by the mines of the

country. Someone said you couldn't begin to describe the Colorado cañon without lying; so I say that any effort to paint the possibilities of our mines would fall so far short of the truth as to be a lie. All I ask for our boys is belief long and strong enough to carry them to Colorado, California, Alaska, Montana, Nevada, New and old Mexico, for I regard Canada and Mexico as part of one great economic unity—the northern part of this wonderful continent.

Before I pass from the mines I can hardly conceal my purpose to arouse interest in our iron deposits. The story of our wealth in the Messaba, Gogebic, Vermilion, and Menominee ranges reads like romance. Read, if you like romance in real life, the story of Peter White and his connection with the mining world of Marquette and northern Michigan. It is vital with all that is worth reading. What is true of Michigan, Wisconsin, and Minnesota is just as true of Tennessee, Georgia, Alabama, and other southern states, but pre-eminently of those named. And what is true of the states in the North, Michigan, Wisconsin, and Minnesota? This: They gave us the world's supremacy in iron and steel. In those states

the iron is in an oxidized form, and has to be gotten out by means of great steam shovels. These lift the ore, pour it into steel or iron freight cars, and these at times, by gravitation, glide down to the world's largest ore-docks in the world, and pour their contents into 10,000- or 12,000-ton steamers, loading in as many hours now as it took days ten or twenty years ago for boats of 2000 tons. These leviathans of the lakes, loaded with the ore, steam to Buffalo, Toledo, Chicago, Cleveland, and other lake cities, unload into cars that carry the contents to the mighty maws of the roaring furnaces which in a few hours convert the ore into that which is to serve for the watchsprings of Waltham and Elgin, or for the steel bridges of Pittsburg, or the locomotives and steel ships of Philadelphia. Was romance by Dumas or Dickens ever more fascinating than the story of the iron ore as it leaves the forests of the North under the pale light of the sun or stars?—as it leaves furnace or foundry a glowing mass warm with the vital forces and functions of the genius of man?—as it leaves the factory fashioned into the myriad forms of steel and iron? That is a part of the story I have tried to tell.

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

SUBSCRIPTION PRICE, including postage, \$1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, Canada, and Mexico. To other foreign countries, \$1.75 a year.

Original contributions, society reports, and other correspondence intended for publication should be addressed to the Editor, Lock Box 1615, Philadelphia, Pa.

Subscriptions and communications relating to advertisements should be addressed to the BUSINESS MANAGER of the DENTAL COSMOS, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, JANUARY 1907.

EDITORIAL DEPARTMENT.

A QUESTION OF JOURNALISTIC ETHICS.

It would seem that one styling himself M. Vernon Ponsonby, presumably a British product, has written a "little book" entitled "The Preposterous Yankee," and that the *General Practitioner*, an English medical periodical, has recently reviewed it, or at least that portion of it relating to "The Preposterous American Quack Doctor," and American dentists. We have not seen the book in question, and its existence would probably have escaped our attention had it not been for the fact that the *British Journal of Dental Science* devotes three and one-half of its pages in the issue for October 15, 1906, to republishing the rot uttered by its medical cotemporary in review of the Ponsonby book.

Under ordinary circumstances the self-respecting course of procedure would be to treat such a manifestly dishonest vilification with dignified contempt; but when a dental publication with any pretensions to decency or ethical standing not only admits such a libel to its pages, but voluntarily selects it from another journal and reprints it, the evidence is conclusive that its editor

is in sympathy with the sentiments expressed and as an accessory to their utterance is responsible for their intent and effect.

We omit the major part of the matter and confine our attention to the strictly dental allusions, as follows:

English dentists will read the following with amusement and agreement: "We have heard a great deal in England about the cleverness of American dentists. Some of these dentists come to England; we are sorry, but they do. They paint enormous signs outside their offices and put up huge notice-boards on which copies of the stars and stripes are painted. They then proceed to advertise, boast, and brag. The American dentist is an excellent blacksmith. He knows how to saw, and he knows how to tinker, file, and solder. One of his specialties is to bore holes in sound teeth and then fill them up with gold. He cares very little about his art for art's sake. His business is to yank out teeth at so much a tooth, to put on crowns at so much a crown, and to work wholly and altogether from a standpoint of the journeyman bricklayer or plasterer."

Mr. Ponsonby does not let the dentist rest. Later on he says that an English dentist who was asked to supply a lost tooth for a pug dog would resent the proposition. "He might even administer a punch in the eye to the person who made the suggestion. He would regard it as unprofessional. But the American dentist would grab the dog and fill him full of teeth and vulcanite him in five minutes. In fact he regards it as rather a feather in his cap, because usually he can get a good notice of the event with a picture of his father, mother, wife, deceased mother-in-law, and the house in which he lives, in one of the five-cent Sunday papers. For the same reason he will often bribe an actress to permit him to set a diamond in one of her front teeth."

We are not concerned with M. Vernon Ponsonby, the author, for his utterance of the foregoing, the internal evidence of which indicates pretty clearly that the *motif* of his literary dash for personal notoriety is of the same character as would have made him the typical "preposterous quack doctor" had he elected the medical or dental channel rather than that of writing as the medium for the public display of his talents. What we do object to is that the *British Journal of Dental Science* has dropped from the standards of editorial decency to a plane where such stuff can find a welcome to its pages—stuff that is neither British—thank God!—nor is it Dental Science. No other dental periodical in Great Britain with the exception of the *Edinburgh Dental Student*, an undergraduate paper, has noticed the Ponsonby effusion, and we should be sadly out in our estimate of the status of ethical dental journalism the world over if any reputable periodical should open its pages to such a libel upon the dental profession of any country. Imagine the *Journal of the British Dental Associa-*

tion, or the representative dental journal in any nation, defiling its pages with such matter.

The ways of the quack and impostor are dishonest and obnoxious in any country, and unfortunately, like all the other multitudinous varieties of dishonest humbug, he exists everywhere. He existed in dental form in England even before the discovery of America, and some of those early English specimens were among the first to bring dentistry, such as it was, to the then British Colonies in America. Quackery flourished in England and overran that land before the phrase "American dentistry" was coined, even before there was any material from which it could be coined. The Colonial American papers are filled with the blatant announcements of dental quacks who hailed from England and introduced their methods throughout the newly settled Atlantic coast region, whose inhabitants they fleeced and whose dentures they ruined without let or hindrance for generation after generation. These dental highwaymen were, however, but the overflow which the home competition due to larger numbers drove across the sea in search of a less cultivated field for their irregular practices. So intolerable had English dental quackery become in the land of its origin that it eventuated in that organized effort made by the immortal group of English professional pioneers to overthrow or at least bring under legalized control this disgraceful state of affairs by means of the historic "reform movement" of 1856—just fifty years ago.

Anyone who may be impressed with the idea that dental quackery in England is an American importation will have his views corrected by a study of the records of English writers on the subject, most illuminating of which is the excellent "History of the Dental Reform Movement," by Mr. Alfred Hill. Referring to a period some thirty years previous to 1877, the date of his writing, he states:

It may be safely affirmed that . . . the great bulk of dentists practicing in the United Kingdom, of whom there were some hundreds, were as a class sadly lacking in scientific knowledge. Scattered throughout the cities and towns of our land were to be found those who evidently had no idea of what a profession as such demanded at their hands. Many had entered upon the practice of dentistry as means of obtaining a livelihood only, and had not hesitated to combine with it a trade of some sort or other, in order to secure a larger emolument than dentistry *per se* would bring them. Others again had abandoned their former calling for this one, under the impression

that it was an easy and simple thing to be a dentist. The author has heard of those who had been milkmen, watchmakers, etc., who had no scruple in posting the words "Surgeon Dentist" on their door-plates, in the hope of making passers-by believe they were what they thus professed themselves to be. Advertisements were plentiful, and the most wonderful announcements constantly appeared in the daily press, setting forth the marvelous ability and fascinatingly low fees of these dental magicians. Others, again, openly displayed their tradesmanlike principles by keeping shops for the exhibition of anatomical preparations, casts of mouths, and metal-gilt dentures, and in some cases wrote up their names in decayed teeth. Sober-minded and really respectable men who hoped by honourable effort and proper professional conduct to advance their position, felt it to be a reproach when called by the name of dentist.

This, according to Mr. Hill, was the state of affairs in the period about 1847.

That English dental quackery of the "home-grown" variety was still enjoying a thrifty if obnoxious existence in recent times, notwithstanding the effective work of the reform movement of 1856, is well in evidence by the publication of a book in 1875, reciting in narrative form the methods and characteristics of the English dental quack, under the title of "Vernon Galbray, or the Empiric: The History of a Quack Dentist." Though published anonymously, its authorship was subsequently publicly avowed by Felix Weiss of London. In his preface the author states: "An endeavor to expose the disgraceful frauds practiced on the public by the horde of charlatans who call themselves dentists is the aim of this little book." It is noteworthy that no reference to the American dental quack occurs in Mr. Weiss' book, and that the typical quack taken as the central figure of the story was rather felicitously conceived by the author as originally a Rotterdam Jew, Samuel Levi Moses by name.

From the foregoing and other data to which we have not the space to make reference, we are of opinion that dental quackery is not of American origin, neither is it an American monopoly; further, that in its original form American dental quackery was a British exotic. Indeed, there is fully recorded one of the historic instances of the importation to America of one of the most notorious of these gentry—James Mallan of the Mansion House and Fleet Street, and his subsequent deportation to his native land, as set forth in the *Forceps*, 1844, pages 6 and 36; also *American Journal of Dental Science*, vol. iv, 1843-44, page 71.

But the quack is facile, whatever his nationality or whatever

his department of activity. Quick to seize upon any suggestion or device that will further his nefarious purposes, the dental quack has found that "American dentistry" is a phrase which skilfully utilized in the humbugging of the public will bring to his coffers an increased flow of the coin of the realm; *ergo*, he works the phrase for all the seductiveness there is in it, and consequently, from one end of Europe to the other it is flaunted in the view of the inhabitants and travelers by swindlers who never have crossed their own frontiers, and whose dentistry (?) has about as much claim to an American flavor as has the dope called a Manhattan cocktail sold over the so-called American bars throughout Europe.

We are without statistical data on the point, but it would be really interesting to know how many simon-pure American dental quacks are quacking outside of America; but even though we lack exact information, we are strongly of the opinion that by far the larger proportion of those who so advertise themselves in Europe are native, home-grown, of the ancient, hoary stock who are still working the same old confidence game by the same general methods upon a gullible public—so gullible at times that not a few who ought to know better are willing—together with an exceptional few who are anxious—to believe that they are what they profess to be when they call themselves American dentists.

We presume that the editor of the *British Journal of Dental Science* knows the general facts of the situation. At any rate we assume that it is part of the business of a dental editor to be informed as to the general accuracy or otherwise of the matter which he allows to go to print in his journal. The representative body of the dental profession in England, as in all countries, knows and deplors the demoralizing effect of quackery upon the growth of our profession, and earnest men with the good of dentistry at heart are using every legitimate effort to stamp it out root and branch. But it is the first instance within our knowledge where a reputable dental periodical has given countenance to such a wholly untrue and libelous utterance directed toward a professional body which, while regretfully bearing its full share of the burden of odium which the quacks and professional camp-followers have cast upon it, still points with a pardonable pride

to some of its achievements—not the least of which was the inauguration of those forces that gave the first impulse to the organization and establishment of the profession of dentistry upon a professional basis.

BIBLIOGRAPHICAL.

LECTURE-NOTES ON CHEMISTRY FOR DENTAL STUDENTS. Including Dental Chemistry of Alloys, Amalgams, Etc., Such Portions of Organic and Physiological Chemistry as Have Practical Bearing on the Subject of Dentistry. An Inorganic Qualitative Analysis with Specially Adapted Blowpipe and Microscopical Tests, and the Chemical Examination of Urine and of Saliva. By H. CARLTON SMITH, Ph.G., Austin Teaching Fellow in Dental Chemistry and Lecturer on Physiological Chemistry at Harvard University Dental School. New York: John Wiley & Sons. London: Chapman & Hall, Limited. 1906. Price, cloth, \$2.50.

We have frequently expressed our belief in the importance of a thorough training in chemistry as one of the essentials of the equipment for intelligent dental practice, and we hail with pleasure any earnest effort to improve chemical training in dentistry, either as to its extent or its thoroughness. A knowledge of chemistry is not only at the foundation of all the material and constructive aspects of dental practice, but no one today can have an intelligent understanding of physiology or pathology, not to speak of the complex problems of nutrition—unless he have a good working knowledge of the chemical processes upon which these subjects are based. Teachers

of dental classes have been heretofore largely dependent upon general text-books in their work of instruction, so that the special applications of chemistry to dental needs have been rather imperfectly presented, with the result that chemistry has always been regarded by the majority of students as a task to be performed, rather than as an illumination to the greater part of their professional course. The author of the present work has done a real service to dentistry, by bringing into harmonious relation and compact form the principal applications of chemistry to the needs of the dental student. The field is covered with sufficient fullness, while the details are explicit and are set forth with conciseness and clearness.

Some few instances of obscurity, and a few errors due to oversight will doubtless be eliminated in a later edition. In the preface, for example, "The usual equipment of a *dental* laboratory has been borne in mind," doubtless refers to the chemical laboratory of a dental school. On the same page Essig's "Chemistry" is referred to, instead of Essig's "Metallurgy."

At the beginning of Chapter I, the author states, "In the older books we read of the *noble* metals—those unaffected by heat." We know of no old book that makes such a loose statement,

as it is a well-known fact that all metals are affected by heat, though not all become oxidized when heated. At page 76, it is stated that "A pure phosphoric acid can be made from the ortho- acid by heating till the white fumes begin to come off, then heat to redness, cool, and dissolve in H_2O to a thick syrup." The foregoing is somewhat confusing, no direction being given as to what is to be done between the time the white fumes begin to come off, and the time when one is to begin heating to redness. There is no such thing as H_2O and when the solution is made it will not be "a syrup" but a solution of syrupy consistence.

Oxyphosphate of copper (page 77) is introduced as follows: "A preparation by this name, which has been used to a considerable extent in the vicinity of Boston." Well, we forgive him; the author lives there and consequently can't help it.

A number of interesting plates dealing with the crystallographic phase of micro-chemical analysis are appended to the work, and add much to its value. We heartily commend the book to those engaged in teaching chemistry to dental classes, and to all interested in chemistry as applied to dentistry.

MANUEL DE THERAPEUTIQUE DENTAIRE.
ODONTOTHERAPIE.

MANUAL OF DENTAL THERAPEUTICS.
ODONTOTHERAPY. BY CH. L. QUINCEROT, Chirurgien-dentiste, Officier de l'Instruction Publique, etc. Paris: Vigot Frères, 1905.

Dr. Quincerot's little volume is a clearly worded discussion of the subject of special dental therapeutics. The descriptions of the medicinal agents usually employed in the practice of dentistry are arranged in alphabetical order, and contain innumerable practical and

rational suggestions on the treatment of the disorders most frequently encountered in the practice of dentistry.

In the article on the "Therapeutic Indications that Should Precede Dental Treatment," we find a suggestion the clinical applicability of which will doubtless appeal to every conscientious practitioner. In general, says Dr. Quincerot, in order to render more active, more efficacious the action of topical agents upon the mucous membrane, it will be well whenever possible to have the patient rinse his mouth with, or to apply upon the affected area, by means of cotton wool, the following solution:

Ammonia water,	m. xv;
Chloroform water,	5v;
Boiled or distilled water,	3vij;
Essence of geranium or anise seed,	m. v.

This solution, the author adds, possesses the advantage of freeing the mouth of foreign particles, of rendering the saliva more aqueous, of eliminating the salivary mucus which adheres so strongly, especially in cases of stomatitis, to the surface of the mucous membrane; and of clearing the tongue and all surrounding soft tissues of all extraneous matter.

In the article on Chloral Hydrate we likewise discern several valuable therapeutic hints, which although not altogether novel in character are, however, but seldom made use of by American practitioners. He recommends chloral hydrate in the treatment of pulpitis and pericementitis. In the former condition, after isolating the tooth in the usual manner, a crystal of the hydrate is introduced into the cavity and allowed to deliquesce under a soft temporary filling; while for pericementitis the gum area of the affected region should be brushed with a mixture containing glycerin five parts and chloral hydrate one part.

For the treatment of infected root-canals, and under the heading Chloroform the author recommends the following preparation:

Chloroform,	3j;
Crystallized menthol,	gr. iij.

Dr. Quincerot has used this formula with gratifying results in numerous cases of the kind above alluded to.

The articles Anesthetics, Toxicology, and Dental Formulæ are equally as interesting as any of those already referred to, for throughout these and all of the remaining articles the author has en-

deavored—and well succeeded—to present the results of his clinical experience and that of many other practitioners and investigators of universal renown, in language the clearness of which is justly deserving of commendation. It is regrettable that the usefulness of the little work should of necessity be limited to those conversant with French, the language of the author, for otherwise we should not hesitate to recommend it to all dental practitioners as a useful, practical, and refreshing reminder of the possibilities of rational dental therapeutics.

ERYTHROPHLEIN HYDROCHLORID IN THE TREATMENT OF THE DECIDUOUS TEETH. BY DR. A. AUDY, PROFESSOR AT THE ÉCOLE DENTAIRE, PARIS.

After a long period of experimentation with erythrophlein hydrochlorid in the treatment of hypersensitive dentin in the permanent teeth, Dr. Audy has applied it with gratifying results in the treatment of the pain which usually accompanies the preparation of carious cavities in the deciduous teeth. The application of a minute portion of this agent, sealed by means of gutta-percha in a carious cavity of the second degree, i.e. one involving the enamel and a superficial area of the dentin only, for a period of two days, is generally followed by the complete disappearance of the sensitiveness. Fissure cavities in the molars, as a rule so sensitive as to render practically impossible their being properly prepared for the subsequent insertion of suitable fillings, are made perfectly comfortable

by the aid of the medicament in question. In cavities of the molars involving all of the occlusal surfaces, and usually filled up to the enamel border with softened disorganized dentin of leathery texture, the erythrophlein will avert the pain which generally appears after the removal of the superficial layers. In the case of very large cavities, it is well to apply the erythrophlein by means of a piece of blotting paper slightly smaller than the floor of the cavity, and to seal the paper dressing with a small layer of gutta-percha.

The application of this agent in cavities of the deciduous teeth is at no time followed by pain or uneasiness, but when introduced into cavities of the permanent teeth, it usually causes a marked uneasiness—impossible to localize—on the same side of the jaw as the affected teeth. In cavities involving the pulp-chamber and requiring the extirpation of the pulp, Dr. Audy proceeds as follows: At the first sitting he removes as much of the carious dentin as possible, and as soon as the pain

becomes at all severe, he applies a dressing of erythrophlein. A day or two afterward, when all possible hyperemic phenomena have been relieved, he makes a minute arsenical application, which, owing to the depleted condition of the pulp, causes none of the unpleasant symptoms which would otherwise follow such devitalizing dressings. At a subsequent sitting the pulp can be extirpated either *en masse* or in smaller particles. In the latter event, the mechanical treatment should be followed by a dressing of geranium-formol. A few days afterward if no unfavorable symptom has developed, the tooth may be filled "permanently."

The author after describing in detail several cases in which the application of erythrophlein had, as aforesaid, materially hastened and facilitated the treatment, concludes his communication, reviewing the clinical advantages possessed by the agent, and warning his readers not to employ it in direct contact with the pulp, inasmuch as it acts favorably only in those cases in which the pulp is but partially exposed, and is still fairly well protected by a layer of disorganized dentin of varying thickness.

From a previous article on the subject by Dr. Audy, the reviewer quotes as follows regarding the characteristics of erythrophlein hydrochlorid: "Erythrophlein is an alkaloid extracted from the bark of the African tree, the *Erythrophloeum Guineense* (sassy bark, mancona bark). It is an extremely toxic substance with selective influence upon the heart. Injected under the skin of a frog's leg in 2 mgm. doses, it brings about inside of five to eight minutes the complete arrest of the cardiac contractions. The ventricles are the first to stop—the arrest occurring during systole; the auricles soon follow, their cessation of function taking place in diastole. The paralysis of the cardiac muscle is followed shortly after by progressive resolution, death occurring at this time. In the warm-blooded animals, the alkaloid produces convulsions and dyspnea, consecutive to the blood-changes it induces. Post-mortem examination shows the heart soft and filled with blood, and traces of the alkaloid in the bloodvessels. Atropin does not stimulate a heart paralyzed by erythrophlein. Curare retards the effects of the alkaloid."

The United States Dispensatory (17th edi-

tion) refers to the anesthetic power of erythrophlein, stating that "In 1888 Dr. L. Lewin asserted it to be a powerful local anesthetic, whose action is more pronounced than that of cocain. His paper gave rise to an extraordinary controversy, Professor Liebreich of Berlin and Dr. Tweedy (London *Lancet*, 1888), denying the existence of the anesthetic power. Schoeler, Karciok, Goldschmidt, Lipp, and others have, however, noticed a local anesthetic influence, and it would appear that the alkaloid has the property attributed to it. A solution of the strength of one-tenth of one per cent. has been used as an application to the cornea. It must be remembered, however, that the alkaloid is violently poisonous." For additional information on the subject, the reader is referred to the writings of Professor Lipp, and to those of Professor Germain Sée in *La Medecine Moderne* for December 1891.

[*Schweizerische Vierteljahrsschrift für Zahnheilkunde*, Zürich, July 1906.]

TREATMENT OF ACUTE AND CHRONIC SUPPURATIONS WITH CARBOLIC ACID IN COMBINATION WITH GUM CAMPHOR. BY DR. C. EHRLICH, BERLIN, GERMANY.

The author (*Semaine Médicale*), following in the footsteps of Dr. Chlumsky, has carried on a series of investigations in view of determining the antiseptic power of mixtures of carbolic acid and camphor. During the last quarter of the year 1905, the author tested the mixture in a number of cases of whitlow, phlegmon, ulcers of the lower limbs, fissure of the anus, furuncles, erysipelas, tuberculous fistulæ, and infected wounds of all varieties. By comparing the results obtained with the carbolic acid-camphor mixture with those obtained in similar cases with the antiseptic agents ordinarily employed, Dr. Ehrlich has convinced himself of the fact that applications of carbolic acid-camphor mixtures are more efficacious than dressings with any of the ordinary agents employed for the purpose, and particularly so in cases of acute suppuration. All the whitlow cases, which otherwise require from eighteen to nineteen days to reach the stage of absolute cure, healed satisfactorily under the influence of the mixture under consideration in about six days; and ordinary phlegmons in four days on an average, as

against eight days under the usual mode of treatment. Dr. Ehrlich employs a mixture of pure carbolic acid one ounce, alcohol two and a half drams, and camphor two ounces. This mixture differs from that suggested by Dr. Chlumsky in the presence of the alcohol, as the latter's formula is composed exclusively of carbolic acid and camphor. In the application of the carbolic acid-camphor mixture to the treatment of superficial ulcerations and infections, care should be exercised not to employ any form of impermeable dressing material.

[*Tribune Médicale*, Paris, June 5, 1906.]

ON CERTAIN DENTAL DISORDERS
CAUSED BY A DIET EXCLUSIVELY
LACTEAL. By Dr. W. B. PIETKIEWICZ.

Adherence to a milk diet may reflect itself unfavorably upon the teeth proper, and likewise upon the alveolar periosteum and the pericementum. It may induce caries, arthritis, periostitis, and pyorrhea alveolaris. These disorders are often overlooked by the attending physician; but among hospital patients they are less frequently disregarded, inasmuch as in the latter they assume more serious proportions owing to the lack of suitable hygienic care usually observable among such patients. Following the beginning of a milk diet, and often as early as the second or third day, the patient experiences, especially upon taking cold or hot drinks into the mouth or upon inhaling cold air, a very painful sensation in the majority of the lower teeth. This sensation is particularly severe in the necks of the teeth. If the patient should have carious, but painless teeth, they become painful soon after the introduction of the milk diet, the caries progressing without interruption. In addition to the existence of caries in the necks of teeth of a patient on a milk diet, such a course of treatment is likewise responsible for the production of numerous occlusal cavities. Such disorders as arthritis, pyorrhea alveolaris, and alveolo-dental periostitis (pericementitis) are additional dental manifestations of a milk diet occurring with the same frequency as caries. The former also appear a few days after the beginning of the milk diet, and are often practically overlooked, as in the majority of cases they are markedly sensitive only to extreme ther-

mal stimulation, a condition not occurring during the period of milk dieting. It often happens that one or more teeth become loosened, in which event, if proper treatment be not instituted, their total loss will follow soon afterward.

It seems useless to enter into a discussion of the pathogenesis of the disturbances under consideration. Suffice it to say that in addition to the fermentation of the stagnated milk in the mouth causing a disintegration of the hard elements of the tooth, an insufficient degree of vital resistance—usually the case in patients requiring a milk diet—and lack of masticatory exercise are important factors in bringing about the above described pathological phenomena.

[*Schweizerische Vierteljahrsschrift für Zahnheilkunde*, Zürich, July 1906.]

AN INTERESTING CASE OF FRACTURE
OF THE MANDIBLE. BY PROF. E.
MÉTRAL, OF THE ÉCOLE DENTAIRE OF
GENEVA, SWITZERLAND.

The author reports a case of fracture of the mandible presenting unusually interesting features. The case was that of a lady aged fifty-five, who, as the result of a serious automobile accident, had sustained a fracture of two ribs, two fingers, and of the mandible between the right second premolar and the right first molar. Examination of the mouth was with difficulty carried out, owing to the extensive and voluminous tumefaction of the surrounding soft tissue areas. The gum was torn and lacerated over an area of several millimeters, and the second bicuspid was loose and slightly out of its alveolus. The line of fracture was oblique from above downward and from behind forward. All such characteristic symptoms as crepitation, mobility, lowering of the anterior fragment, and elevation of the posterior fragment were present. During the process of reduction the patient suffered almost unbearable, excruciating pain, but notwithstanding the severity of the local symptoms, no general manifestation was detectable. After having obtained suitable impressions of the maxilla and the mandible, and plaster casts therefrom, it was decided by the author to support the fractured organ by means of a gold splint, which was made to accurately embrace all the surfaces of the fourteen teeth in the fractured jaw, and to

fit the occluding surfaces of the thirteen maxillary teeth. The splint was held in position by means of six small screws, which running through the buccal surface of the splint, would engage themselves in the interproximal spaces, and thus hold the splint immovable *in situ*. The splint was in addition suitably perforated at numerous places to permit of the entire affected area being antiseptically treated at frequent intervals. The insertion of the apparatus was accompanied by most severe pain, but on the following day a marked improvement was already noticeable, the patient being then able to take solid food and to enunciate without difficulty.

Throughout the treatment the author kept the mouth in as thoroughly an antiseptic condition as possible by means of irrigations with ten-volume hydrogen-dioxid solution every four hours. A slight suppuration occurred in the lacerated gingival region, and shortly afterward a small sequestrum was eliminated.

The strikingly interesting point about the case under consideration lies in the fact that, notwithstanding the age of the patient, complete consolidation had taken place on the nineteenth day after the accident, at which time it was found that the lacerated—and at first highly inflamed—soft tissues had entirely regained their normal appearance and function; that the teeth were as clean as if they had been brushed daily, and that the articulation had suffered no modification whatever. In concluding, the author remarks that for the treatment of cases demanding the insertion of the metallic splint, 20-k. gold is the material *par excellence* from which to swage the apparatus.

[*Trans. Odontological Society of Gt. Britain*,
June 1906.]

SOME NOTES ON THE RELATION OF
DENTAL CONDITIONS TO PULMONARY
TUBERCULOSIS. BY F. LAWSON DODD,
M.R.C.S., L.R.C.P., L.D.S., D.P.H.

The writer of this communication, because of his connection with the staff of the Metropolitan Hospital for Diseases of the Chest, with its sanatorium for the open-air treatment of phthisis, was led to examine the possible relationship of the general disease tuberculosis with the local conditions obtaining in the mouth of the patient. He calls attention to the fact that increased knowledge

of pathology, and especially of bacteriology, is leading the medical profession to place an increasing significance upon the condition of the mouth as a factor both in the production and prevention of disease.

He refers in general terms to the modern treatment of pulmonary tuberculosis, which consists mainly in the removal of the patient from an unhealthy environment and placing him in such conditions as will favor success in the struggle against disease. The avoidance of all possible sources of infection is achieved by placing the patient in a germ-free atmosphere and keeping his surroundings scrupulously clean. Meanwhile the nutrition of the body is maintained, or aimed at—often unsuccessfully, for reasons to be specifically referred to later—by a plentiful food supply added to as large a measure as possible of physiological rest.

The writer believes that investigation from the standpoint of the dental surgeon will show that a large proportion of the modern treatment of consumption is but a cleansing of the outside of the cup and platter, a system of removing some of the more remote obstacles to progress, while the more intimate and personal dangers are entirely overlooked. He refers to the broad generalization that the human mouth is a perfect breeding-ground for pathogenic organisms, adapted alike by temperature, moisture, and the presence of an endless supply of nutrient material—conditions which make possible the growth and development of a flora of micro-organisms that is extraordinary in its number and variety—a generalization made possible by the researches of Miller of Berlin, Goadby of London, and others. Though Koch's bacillus (apart from its presence in actual sputum from the lungs) is comparatively rarely found—a fact due mainly to its weakness in the struggle for existence against endless foes—the bacterial flora of the mouth contains pathogenic as well as non-pathogenic organisms. In apparently healthy persons the pneumococcus, the micrococcus tetragenus, staphylococcus and streptococcus pyogenes, and the Klebs-Löffler bacillus have all been found. These organisms may all gain entrance to the system by inhalation, swallowing, through abrasions or wounds of the tissue of the mouth, or through exposed and necrosed tooth-pulps. It is not claimed that hygienic care of the mouth will remove all, even of these or-

ganisms, but it will greatly lessen their number, and with that the chances of infection. But whatever may be said in regard to the specific septic infection taking place through the mouth and teeth, there is no doubt as to the existence of secondary anemia, associated with lowered vitality and great foulness of the whole alimentary tract, resulting directly from buccal infection. In such cases not only is there local absorption of toxins from the mucous membrane of the mouth and the alveoli of the teeth, but the infection with staphylococci is a continuous process throughout the alimentary canal. Just as the remedy for chlorosis was said to consist in the cleansing of the lower end of the intestine, so we may claim that the cleansing of the mouth is of equal importance. It is a safe aphorism, Look after the two ends of the alimentary canal, and the middle will look after itself.

He shows by statistical figures that the part played by oral sepsis in the production of phthisis in adults may be repeated with greater emphasis in the case of children. They are more susceptible to diseases of the respiratory organs, and to tuberculosis in particular. And while his observations pointed toward the belief in the simultaneous existence of carious teeth and exposed pulps in the cases of children admitted to the institutions with which he is connected, he states that while we can only draw inferences from such facts, they are sufficient to bring out the importance of removing every possible cause of disease.

The author is more emphatic in asserting the potency of mouth-breathing as a common contributory cause of phthisis. The habit of mouth-breathing in many cases being either a result of carious teeth in early life. An exposed pulp or tender septic gums rendering mastication impossible, the child is afraid to close the jaws, and not only acquires the habit of bolting his food, but also, to avoid possible painful contact with the teeth, keeps them open sufficiently to part the lips, and begins to breathe from the aperture thus formed, while the part played by oral sepsis in enlarging the tonsils will itself favor this dangerous habit. We may reasonably say that whatever influence oral sepsis may have in the production of phthisis, the first aim in its treatment should be the reduction of infective processes and the inculcation in the

patient of the importance of scrupulous cleanliness of the mouth.

The author emphasizes the second factor in the treatment of phthisis, namely, the proper nourishment of the tissues, and calls attention to the important researches carried out in America by Mr. Horace Fletcher on the question of oral digestion and its relation to health and disease. The intimate connection shown to exist between mastication and nutrition emphasizes the importance of carefully considering the condition of the teeth in cases of phthisis.

The nutritional treatment of phthisis must depend upon two factors: (1) The presence of appetite, and (2) the power to assimilate the food taken. Septic mouths, coated tongues, local suppuration of the gums, pyorrhea alveolaris, suppurative periodontitis, all destroy the desire for food by their effect on the mucous membrane of the tongue and fauces, chiefly by impairing taste, but also by infection of the stomach and intestine. In combating these cases of anorexia, attention to the teeth and mouth is all-important.

According to Miller it is erroneous to imagine that organisms bred in the mouth necessarily perish in the stomach. It is certain that normal gastric juice does not destroy the virulence of the tubercle bacillus when swallowed by careless or weak patients with the sputum.

He quotes from Miller ("Micro-organisms of the Human Mouth," page 303) the statement that "In a very unclean mouth examined for this purpose I estimated by culture methods the number of cultural bacteria at 1,140,000,000. Many of these were doubtless carried to the stomach during every meal, to be replaced by others developing between meals and over night." In a well-managed sanatorium an aseptic food supply may have been attained—even the milk consumed may be free from tubercle bacilli; but all these precautions may be a delusion and a snare if the patient, before swallowing his food, is chewing it in such a charnel-house as described in the above words, which unquestionably depict a very common state of things. It is waste of public money to increase the diet in such cases without at the same time insisting on conditions of oral cleanliness among those undergoing the open-air treatment for consumption. It is better in many cases freely to remove diseased teeth than to

leave them in the condition in which one finds them in the mouths of a considerable proportion of our patients.

It is necessary to see to it that patients possess the power to assimilate the food given. The loss of masticating power, with or without the habit of bolting the food, is a serious handicap to the phthisical patient; therefore an important part of the treatment must consist in replacing lost teeth. Where this is not practicable it is well to remember that with soft food much may be done by working it between the tongue and hard palate, so as to thoroughly incorporate it with saliva and give time for oral digestion. This can only be done safely where oral hygiene is duly attended to.

The author quotes a number of authorities and presents statistics to show the relationship between chronic lymphadenitis and diseased teeth, and says that such cases at least warn us of the possibility of serious general infection, breaking through the lymphatic barriers, already lowered in resisting power by repeated attacks or the commoner products of oral bacteria; and it should not be forgotten that the study of the relation between oral sepsis and general disease is at present in its infancy, as is proved by the obscurity that still hangs around the etiology of cervical lymphadenitis.

He does not pretend to say that the evidence for general infection with tubercle through carious teeth is either satisfactory or complete, yet the danger of oral neglect is made at least more serious by the records. The writer calls attention to the possible danger of secondary local infection in cases of pulmonary tuberculosis, and presents statistics from Zandy of thirty-seven cases of alveolar tuberculosis in which infection spread directly in three cases of lupus. In the majority of the remainder the buccal mucosa was first attacked, the condition spreading to the gums and teeth later. In five of the thirty-seven cases tubercular ulcer commenced at the seat of extraction of the teeth. Zandy agrees with Starck that caries of the jaw may result from infec-

tion between teeth and gums, or through the pulp of a carious tooth.

After reporting a number of illustrative cases, the writer says: "I hope to have at least established the claim that our position as dental surgeons is important in connection with the treatment as well as the prevention of tubercular infection, both local and general. It is for us to maintain that all the expensive schemes for the open-air treatment of pulmonary tuberculosis are largely handicapped unless radical measures be taken to render clean and efficient the mouths of the patients admitted. Surgical cleanliness of the mouth and teeth may be reached by proper operative treatment, but this alone is useless unless a rule of cleanliness with regard to the brushing of the teeth and gums be insisted upon, and its execution supervised. Observation has confirmed this necessity."

The points of his communication, as summarized, consist of the following:

(1) Septic conditions of the mouth favor the occurrence of tubercular infection by lowering the vitality and power of resistance, both generally and also locally in the case of the lymphatic glands of the neck.

(2) Dental caries, especially when associated with exposed pulps, may open up channels for direct infection of either bony or soft tissues of the mouth, and either primarily or secondarily.

(3) Neglected mouths may sometimes confuse the diagnosis in cases of incipient phthisis.

(4) In the open-air treatment of consumption, the care of the teeth and mouth generally should be regarded as one of the most important factors making for success.

(5) Costly buildings and great institutions are springing up all over the country, and it is certain that so long as the mouths of the patients are neglected in the present manner, the money of the public is being largely wasted and the percentage of recoveries considerably lessened and delayed for want of proper dental supervision and care.

PERISCOPE.

To Polish Plates.—Use powdered pumice stone moistened with Johnson's ethereal soap, employing either felt cones or brush wheel. It is cleaner than when water is used to moisten the pumice, and will save time.—E. T. EVANS, *Dental Review*.

Cementing Arsenic.—Mix the cement rather thin and place a small drop of it on a bit of paper and carry the paper to the cavity with the pliers; then press to place with a burnisher. The paper facilitates adjustment to place and prevents the cement adhering to the instrument.—C. B. WARNER, *Tri-State Quarterly*.

Sterilization of Dentures.—Sulfurous acid will absolutely deodorize and disinfect a denture, and not merely cover the odor of a plate that has been worn in the mouth. Place a few drops in a little water and immerse the case in the solution at night and cleanse with soap and brush in the morning.—J. KENNERLY, *British Dental Journal*.

Cleaning Files.—When a vulcanite file becomes clogged with rubber and plaster, it may be easily cleaned by wrapping absorbent cotton around it and subsequently saturating the cotton with chloroform. In about ten minutes it can be cleaned perfectly by the use of a stiff brush wheel on the lathe.—V. P. PERISHO, *Dental Review*.

Protecting Porcelain Surfaces for Solder Work.—If porcelain surfaces in bridge work are coated with sandarac varnish before investing, and care is taken to have the investment thoroughly heated before beginning soldering, it will result in little or no cracking or checking of the porcelain.—HENRY C. LEE, *Dental Review*.

Treating an Alveolar Abscess Through the Alveolar Process.—I believe it is a mistake to carry a tooth along through weeks and weeks of treatment through the pulp-chamber, and many of us make a mistake in treating teeth too often. Whenever an abscess forms about a root, it nearly always surrounds the apex of the root. It destroys the peridental membrane around the sides of the

root, consequently treatment through the root-canal does not effect our purposes, and after pus has been present some time, if the surface of the root has been bathed in pus for many weeks, we will get satisfactory results from treatment through the pulp-chamber in very few cases. I do not practice immediate root-filling in such cases, but I have done it "more immediately" than is the general custom. In such cases I prefer to fill the root-canal, and, if necessary, make an opening through the alveolar process.—ARTHUR D. BLACK, *Dental Review*.

Method of Inserting Crystal Gold in Combination with Foil Gold.—How many dentists in using crystal golds have taken advantage of the ease of adaptability of some of these forms of crystal gold to a cavity by using them in connection with foil or heavy gold, placing a mass of crystal gold relatively in position, and over it a mat of foil or plate of rolled gold to facilitate the carrying of the crystal accurately to place *en masse* without the chopping up that is apt to occur in my hands with any form of crystal gold? It seems to me there is a saving of time and of gold, and facilitation of the packing, by using alternate layers of crystal gold and foil in some form, combining in this way the virtues of foil and crystal. —W. V-B. AMES, *Dental Review*.

Practical Thoughts on Impression-Taking.—While modeling compound at the time of its advent was hailed as a substance of marked value for the taking of impressions, and while it is still in favor for many prosthetic purposes, experience has proved that it cannot be used to advantage where great accuracy in reproduction is necessary, as in the making of either entire or large partial dentures. Plaster of Paris either alone or in combination has entirely superseded all plastic materials, and no rival to it has appeared. In the manner of working it and bringing out the best qualities, experience has developed several improvements.

Where sodium chlorid was formerly employed to hasten the setting of ordinary or slow-setting plaster for impressions, it is now recognized that the best results are obtained by using the quick-setting variety without the

addition of any chemical. While the combination of a wax or modeling compound base and a top layer of plaster was once much in favor, the difficulty of accurately replacing broken portions of the impression has greatly lessened its employment. The placing of a wax guard along the posterior border of the tray, however, is one of those minor devices which has proved to be of the greatest value; not so much for the purpose of preventing the plaster from extending too far back upon the palate, for which it was first suggested, as for the compression of the soft tissues at a point where the plate terminates. Experience has demonstrated that plates made from such impressions are best adapted for the exclusion of air at this vital point.—S. H. GUILFORD, *Stomatologist*.

Devitalizing Pulp.—Arsenic, if properly sealed in a cavity and left long enough, is much more satisfactory than pressure anesthesia to both the patient and operator, unless the case be one of emergency, and then no doubt pressure anesthesia is the method to use. We were taught in college to leave arsenic in a tooth from twenty-four to thirty-six hours only. I am quite convinced that allowing such a limited time for the arsenic to do its work is the reason so many young practitioners are sorely tried by having patients return too soon, and upon opening into a tooth, find the pulp still vital or partially so.—W. E. O'KEEFE, *Dental Review*.

The Mixing of Amalgam.—I have much fault to find with the prevailing method of amalgamating alloys. If we are to start out with a homogeneous alloy, we should wind up with a homogeneous amalgam. The very best grades of modern alloys do not combine readily with mercury, and even after the combination of the metals has been effected there remains within the mass a large surplus of mercury, including a fair percentage of particles of alloy which have not succumbed to the action of the mercury. During the process of wafering the amalgam, also including its insertion in the cavity, there remains in the amalgamated mass a large percentage of free mercury, together with a lesser proportion of unamalgamated alloy; and so in time two evils are bound to develop in the way of shrinkage and lack of permanence of form. The shrinkage is due to the surplus of mercury, while the slight change of form is the result of particles of alloy acting upon the free mercury, thus causing a change in the crystalline structure of the amalgam. The only remedy we have for such trouble is to spend more time in mixing the alloy; such as

tritulating it with a faint surplus of mercury and removing the surplus of that metal by using gentle pressure. Return the mass to the mortar or the palm of the hand and work it vigorously until it has re-softened. Wafer again, and continue the kneading and wafering process until, all told, four operations have been performed. You will be surprised to find how much more mercury will be removed from the mass when working your alloy in this manner. You will also succeed in producing a homogeneous amalgam, with the exception of a certain percentage of free mercury that can only be removed as the amalgam is inserted in the cavity. When the mass of amalgam is large the final wafering process should be performed by dividing it into several portions and wafering each one separately.

The success attained in producing a good mix does not depend upon the amount of mercury that you use as much as upon the amount that you succeed in removing from the mass.—N. K. GARHART, *Dental Era*.

Prevention of Air-Spaces in Vulcanized Rubber.—The expansion of rubber by heat between 200° and 320° is a very close approximation to its shrinkage, therefore, if, after the flask is closed by boiling it, the bolts are slackened so that the flask will part easily under the pressure caused by the expansion of the rubber as it is heated to the vulcanizing point, all the rubber which was in the mold when it was closed can be retained therein. Then, if spring pressure be applied, and the flask closed after shrinkage has practically ceased, the rubber will, at the end of the vulcanizing process, remain closely applied to the teeth and the surfaces of the mold.—GEO. B. SNOW, *Dental Brief*.

Removal of a Broken Gates-Glidden Drill.—Many are lucky enough never to break a Gates-Glidden drill only where they are intended to break—up near the shank. Not long ago, in cleaning out an upper lateral, my Gates-Glidden drill broke off, leaving about a quarter of an inch of drill in the tooth. After failing to get it out by the use of pliers, etc., I stepped over to the stock room of a telephone company and borrowing a large horseshoe magnet, magnetized another Gates-Glidden drill by allowing the drill to rest on the magnet for a short time; placed the drill alongside the piece still in the tooth, worked the one thus magnetized around in the tooth to be sure there was a good contact; removed the Gates-Glidden and the broken piece came out with the magnetized drill.—DEWEY D. SMITH, *Dental Summary*.

Perhydrol (Hydrogen Dioxid) in Dental Hyperesthesia.—Viggo Andresen of Copenhagen (*Deut. Monatsschrift für Zahnheilkunde*, January 1905), states that a few drops of the 30 per cent. hydrogen dioxid (perhydrol) of Merck acts almost instantaneously in anesthetizing the dentin. It is to be preferred to silver nitrate, since it bleaches instead of staining. In filing off long teeth much pain can be avoided, but for the pulp itself the drug is entirely too irritating. In cavities that cannot be kept dry, it also serves to disinfect, while the cauterization is too short in duration to be harmful.—S. H. GUILFORD, *Stomatologist*.

Bent-Wire Clasps.—The greatest improvement in clasps as plate supporters consists in forming them of round or half-round platinum gold wire, bent upon itself, or doubled and so shaped as to include in its grasp as much of the circumference of the tooth as clasps usually do. This open or bent-wire clasp, by its form, possesses the peculiar advantage of having one of its folds just above the greatest diameter of the crown, and the other just below it. By this means the tooth is not only more firmly grasped, but the clasp by virtue of its shape can neither slip up toward the gum nor down toward the occlusal surface. This form of clasp is far more correct in principle than the former kind, where the flat surface of the clasp, in contact with the convex surface of the tooth, was intended to afford the desired resistance.—S. H. GUILFORD, *Stomatologist*.

Hard Mucous Surfaces: How to Modify them in the Impression.—In a former paper I referred at length to certain difficulties which often occurred in the fitting of artificial teeth, owing to the unequal conditions of the mucous surface of the mouth. We will suppose that we have before us an edentulous mouth, hard and bony in the central line of the palate, while the sides and alveolar ridge are soft and compressible. It will be found that a case perfectly fitted to this mouth would, under pressure of mastication, bear first—and unduly—on the surface which is hardest, viz, the bony ridge, with the result that it would rock, cause pain, and fail in suction. My manner of procedure is as follows: First examine carefully the mouth. Note the extent of the hardness as compared with the surrounding parts, then take a sheet of absorbent fiber lint paper, such as we use for drying out cavities, and which consists of about four distinct layers. Cut out with sharp scissors a piece resembling in shape the hard surface, strip the

paper to the desired thickness, and place over the bony surface. Immediately deposit upon this a small piece of softened compound, about the size of a button, and press into position. The floor of the roof being thus covered the model must be completed in the usual way. On withdrawal, it will be found that the "paper" will be enveloped in the substance of the modeling compound. Before pouring the model with plaster, wash out the paper. When the model is poured it will be seen that over the hard and bony part of the mouth is a raised surface, which in the finished denture acts, to some extent, as a suction cavity, but which absolutely prevents undue bearing and rocking on the bony surface, and results in a general distribution of the pressure of mastication on all parts of the mucous surface.—J. C. OLIVER, *British Dental Journal*.

Methods of Diagnosis: The Exploring Needle and the X Ray.—The exploring needle in the hands of a skilful dental surgeon whose touch has been "educated" locates hidden roots, abscess cavities, necrotic tissues, and phagedenic destruction of bone. Its revelations are swifter and surer, under some conditions, than those of the X ray.

In locating misplaced and unerupted third molars the X-ray method is unequaled. But there are comparatively few dental surgeons provided with the facilities or equipped with the skill and training in the art of skiagraph pictures necessary for formulating an accurate diagnosis by this means. No one will dispute the value of this insight into the hidden things of nature; and when all other means have failed to give the operator a fairly clear mental picture of the case, before proceeding we should resort to this, even if it should be necessary to call in the aid of a specialist in the work.—L. G. NOEL, *American Journal*.

The Therapeutic Value of Mastication. It has long been recognized that the oral cavity constitutes an important factor in the physiology of digestion, and this importance is increased by the knowledge—now so universally prevalent—that many chronic diseases are directly dependent upon auto-intoxication originating in the intestinal tract. The part which the mouth and its accessory structures play in digestion is in fact of equal value with that assumed by the remaining portions of the alimentary canal, and this is of particular significance, because it is here that the only part of the process resides which is under voluntary control. The oral cavity is concerned with the mechanical disintegration of the food, it regulates the temperature of the latter, and provides an admixture of sa-

liva which, aside from its lubricating function, affords a means by which the organs of taste are excited and the digestion of the carbohydrates begun. Pavloff has pointed out that the sensation of palatability conveyed by this means has an important psychical effect on the secretion of the gastric juice, and in addition, the peripheral stimulation of the gustatory nerve increases the potential energy of the entire nervous system. Montlouis and Pascault (*Journ. des Praticiens*, No. 3, 1906), following Fletcher and Chittenden in their modification of Cornaro's practice, believe that this knowledge can be made of great practical value in the treatment of certain diseased conditions. Thorough mastication, it is quite evident, will serve to make even small quantities of food more efficient and sustaining. In addition to this, the assimilation of otherwise indigestible material is favored, and the remaining portions of the alimentary tract are relieved of a certain amount of labor. Systematic mastication, therefore, they regard as of particular value in dyspepsia and auto-intoxication; arthritis and neurasthenias of various types, which are believed to depend on the latter, will consequently be especially benefited. Even when the diet is limited to fluids, the suggestion also holds good in a way, for in this case it is advised that the nutriment be taken in small quantities at a time, in order to gain the same advantages in the way of gradual introduction into the stomach and mixture with saliva which would otherwise be produced by the act of chewing.—*Med. Record*.

How to Take an Impression of a Soft and Flabby Mouth.—In some cases the arch is soft and flabby, and in some the ridge, if not gone, is soft and yielding; in extreme cases no bony parts exist at all. In such instances it is a question of science to construct such a denture as shall be useful and of some comfort to the wearer. If we make a plate over the parts as they are, it will fit only so long as we do not use it. But the moment we try to masticate, and the pressure necessary for that function is applied, it will necessarily dislodge the plate. Here plaster is contra-indicated as a material for impressions; and the softer the mouth the more it is unfit for the work. We do not want an impression of the tissues as they are, but as they would be after pressure upon them is applied. Many of our patients in this class of cases will tell us, "Doctor, the plate stays in place until I start to eat, and then it comes down;" whereas if you had considered that the soft tissue is subjected to considerable pressure in the act of eating, in order to make the plate stable you would have had it fit when

the tissue was compressed. My plan for taking impressions of mouths extremely soft is to take the best possible impression in modeling compound, then chill it until set, and trim out the entire surface to a depth of about one-eighth of an inch. Then warm up and soften more compound, and spread it evenly over that already in the tray. I usually select S. S. White compound to get the first impression, as it takes a little higher temperature to soften it, and it does not become quite so plastic. Then for the second batch I employ a quick-setting, lower-temperature compound, as the Detroit, or some other similar make. When this is put in for a final impression it should be quickly handled, not to chill in manipulating or to heat up the first compound used. It will take some pressure to secure the impression, as the tray and the first compound used will act as a matrix to hold together and confine the second and softer preparation; force it well against the tissue, taking advantage of all the compressibility of the tissue possible. Plaster in these cases does not fill the bill, for if we exerted enough force to compress the tissue it would be pressed out of the tray, and parts of the mouth would be in contact with the tray.—E. M. KERRIG, *Dentist's Magazine*.

Pulmonary Abscess Caused by a Tooth.

—A. C., a young lady who consulted me, stated that she had been ill for about seven months. She complained of pain located in the right side of the chest, together with severe cough and profuse expectoration. Her previous health had been very good. About seven months previously she began to cough. This was accompanied with pain in the right side of the chest, and soon afterward with expectoration of thick phlegm. She had difficulty in breathing. These symptoms increased in severity, and the patient lost a great deal in weight. She consulted several medical men, and was treated at the Swansea Hospital as a case of phthisis pulmonalis. Her condition did not improve. When I saw her, she appeared very ill, and was quite unable to leave her bed; perspired freely, and was much emaciated. Her temperature continued at 101°. The cough was very troublesome, and accompanied with expectoration of fetid pus. The movements on the right side of the chest were very much diminished. Vocal fremitus was diminished on the right side of the sternum. There was extensive dullness from the right clavicle to the fourth rib. The apex beat of the heart was displaced downward and to the left about 1½ in. There was undoubtedly an abscess in the lung. Three days after I first saw the patient she had a very violent fit of coughing, with a discharge of a

large quantity of pus from the lungs. On examination of this there was found a second bicuspid which she had had extracted by a dentist about seven months previously. This tooth must, of course, have been drawn into the glottis while she was under gas—although she was quite unaware of the fact—and lodged in one of the divisions of the right bronchus, where it caused the formation of a large abscess.

After this the patient made an uninterrupted recovery. The lung was healed up. Owing to the contraction of the lung, the heart has been drawn considerably to the right side, the apex being at least one-half inch to right of normal.

It was undoubtedly a very lucky chance which led to the expulsion of the tooth from a large cavity through what must have been a small opening, but this must have been due to the tooth being carried in the current of the thick, purulent contents of the cavity toward this small opening.—JOHN D. DAVIES, *Brit. Med. Journal*.

Treatment of Sensitive Cavities: Carbolic Acid—Sodium Dioxid.—There was a discussion at the August meeting of the American Dental Society of Europe on this subject, in which Dr. Bogue of New York, told us he used pure carbolic acid first in the cavity and afterward zinc chlorid. I have been experimenting for some months with sodium dioxid, and now, having utilized Dr. Bogue's hint about using carbolic acid first, I find I can control very troublesome cases with not too much previous pain. For three or four years I have used very finely powdered sodium dioxid for relieving sensitive places on the necks of teeth, or spots rendered sensitive by contact with gold bands supporting plates. This led me to use it occasionally for troublesome cavities. My present method is: Flood the cavity with pure carbolic acid, and wait a minute or so; then, without wiping out the acid, put into the cavity a little finely powdered sodium dioxid. This causes some pain. Add a few more grains, and commence to carefully excavate. If the rubber dam is not used, care must be taken of the gum.—HENRY I. MOORE, *Dental Review*.

How to Determine the Direction of the Condyle's Path.—To find what is the direction of the condyle's path in a patient, the dentist may proceed thus: Having taken the articulating impression in the usual way—this method cannot be used with the squash bite, unless in connection with the true-bite plates—and before removing it from the mouth, let him ask the patient to protrude the mandible as far as possible—which will

be about a half inch—and then to close it again. If the patient's condyle path inclines downward the two planes of wax will now meet only in front, but if it is horizontal they will remain in full occlusion with each other. If the former, the amount of their opening at the molar region may be determined by inserting a knife-blade or small stick of wood, marking its position—also marking the extent of protrusion—so that when the articulating impression is transferred to the articulators, and a similar protrusion is made on them and the knife-blade or stick is inserted in the same place, it can be readily seen if the articulator's mechanism representing the condyle's path needs adjusting to suit the case.—STEWART J. SPENCE, *Dentist's Magazine*.

Methods and Equipment for Bedside Dental Treatment.—It is my practice to make clinical visits either early in the morning, at the noon hour, or in the afternoon after regular office hours. There are times, however, when the case is being seen in consultation; in that event the hour must be arranged with the physician or consultant. My assistant accompanies me, being even more useful there than in the office in setting up the dental engine, arranging the instruments, and assisting in the treatment. Regarding the apparatus: It consists essentially of a physician's operating bag carrying a modified dental engine, operating instruments, and mouth-illuminating apparatus. The instrument case is one known as the half-cabin physician's bag, about 17 inches long and 6 inches wide. The lower portion is removable, and contains instruments, trays, and a complete set of half-ounce glass-stoppered medication bottles, while the upper portion carries the engine, illuminating apparatus, and other larger objects. The portable dental engine is a most important part of the equipment. Your experience must have been that in more than 50 per cent. of these bedside treatments, the operation of opening up the pulp-chamber or root-canals is involved, and the ineffectual struggle to accomplish this without the dental engine is most annoying. I have therefore constructed a hand engine, which, while not especially rapid or powerful, serves all purposes.

The engine equipment is carefully selected to furnish the sharpest and most rapid-cutting burs. A full set of Beutelrock hand and engine root-canal instruments has been of the greatest use. The broaches, canal-dressing instruments, and pluggers are just as important. The explorers, scalers, extracting forceps, elevators, crown-slitting instruments, mouth-props, and most of the other larger

instruments are transferred from the office operating room to the carrying case at the time of the visit. They are sterilized in the office, and placed in sterile towels which have been sewed into pockets, so that they may become instrument rolls, easily washed and sterilized for each visit. Napkins, cotton rolls, and a saliva-ejector operated by a hand-bulb are always taken. A hypodermic syringe, ethyl chlorid tube, and other apparatus for local anesthesia are included.

The subject of a general anesthetic for any case requiring it is one solved either by the dentist or the attending physician. I have a portable nitrous oxid apparatus available at all times, and the somnoform equipment has

also been found satisfactory and compact. Of course the materials and instruments for making temporary fillings and dressings and oxyphosphate fillings are necessary, but permanent forms of fillings are not attempted. A small surgeon's case of lancets and probes is carried in the upper portion of the bag, and a reliable alcohol lamp is included. Where it is known that the residence visited is using the incandescent current for illumination—as is the case generally in Cincinnati—I include a sixteen-candle-power lamp with reflector and handle, and a good length of cord with socket plug. An electric battery hand-lamp is provided when current is not available.—H. T. SMITH, *Dental Summary*.

HINTS, QUERIES, AND COMMENTS.

REMOVABLE POSTS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—On page 1192 of the December 1906 issue of the *Cosmos*, you give Dr. Charles Taylor's idea in regard to posts that may be removed easily and without injury to the root. Dr. Taylor advocates a hollow post, and explains a very crude method for producing it.

The easiest and most practical method of making an article like this is the old, almost ancient mode of making hollow wire, which consists of drawing a piece of plate through a draw-plate, and the procedure is so simple, that it seems strange any other way is suggested.

Having cut a strip of metal about three times the diameter of the proposed post, bend up its edges until it is in the shape of an old-fashioned eaves-trough, then push it together at one end, and cut it in a slanting manner, so that this end may pass into the larger hole of the draw-plate, and be grasped by a strong pair of pincers and pulled through. This is easily accomplished if the metal is first rubbed with beeswax. By passing it through the holes, each a little smaller than the preceding, the tube is made, and can be soldered or not. It is best, however, to solder it before the final drawing, as that will give a smoother surface.

By continual drawings, a tube of any size may be produced. Of course it requires a

draw-plate of larger size than is usually found in a dental office. The largest hole in my largest plate is about the size of a No. 6 wire. But how many dentists possess a draw-plate of any kind, or know how to use one? And yet there is no tool for the laboratory more useful. To illustrate this fact, let me tell of a difficulty from which I escaped: A bridge with a loose facing was brought to my office; the pins of the facing were broken but not "started" in the porcelain. There was not a proper tooth for the case to be found in the city.

The stumps of the pins protruded just above the surface of the porcelain. I made a tube of platinum that would fit over these stumps, and bending it in the form of a U, placed the ends of this U on the pin-stumps, waxing them to place; then invested the whole in plaster and sand, laying a piece of iron wire across the sound part of the U to hold it when the wax should be removed. I then soldered this U to the pin-stumps, and cutting the bottom of the U, I had a tooth with two good pins.

In regulating appliances, and in many other things of use in our profession, a draw-plate is of inestimable service. Few know that with a draw-plate, a firm vise, and a strong pair of pincers, a wire one-eighth of an inch can be drawn by hand.

JAMES H. BEEBEE.

Rochester, N. Y.

OBITUARY.

DR. C. R. TAYLOR.

MEMORIAL RESOLUTIONS ADOPTED BY THE ILLINOIS STATE BOARD OF DENTAL EXAMINERS.

Whereas, On roll-call at the opening session of the November 1906 meeting of the Illinois State Board of Dental Examiners, the name of Charles R. Taylor receiving no answering response makes us pause to pay tribute to his worth and memory. Little did we think at our last parting that at our next meeting our long-time friend and co-laborer, strong in all the elements that constitute a lovable man, would be beyond the reach of voice, and his chair stand vacant at our table—reminding us that the strongest ties of friendship must sooner or later be broken, but not forgotten. In token of our affection and appreciation of Dr. Taylor's influence in private and public life for the betterment of all who had the good fortune to know him, it is hereby

RESOLVED, That a page of our records be set apart, and the sentiments herein expressed be inscribed thereon.

DR. C. S. BECK.

MEMORIAL RESOLUTIONS ADOPTED BY THE PENNSYLVANIA STATE DENTAL SOCIETY.

Whereas, We, the friends, *confrères*, and fellow practitioners of the late Dr. C. S. Beck of Wilkes-Barre, have learned of his death; and

Whereas, We deeply regret the loss of our distinguished co-laborer and warm-hearted friend, to whose energetic life we owe so much in the advancement of dental science and organized society work; and

Whereas, By his labors this and kindred societies were advanced and the profession at large benefited; therefore be it

RESOLVED, That it is with deep and sincere regret we have learned of his death, and tender to the family our sympathy and deep sorrow; and, That a copy of these resolutions be sent to the family and spread upon the minutes.

DR. H. D. HARPER.

DIED, at Wilson's Sanitarium, N. C., Saturday, November 24th, as the result of an attack of pneumonia, H. D. HARPER, D.D.S., in his sixtieth year.

Dr. Harper was born in Johnson county, Bentonville, N. C., May 4, 1847. His father, John Harper, was a prominent planter. His youthful days were spent upon his father's farm, until in 1864, when seventeen years of age, he entered the Confederate army as a member of Griswold's Independent Company of Goldsboro. He was in a short time detailed as a courier to Col. Stephen D. Poole, and served in that capacity through the remainder of the strife, except that in the battle of Cobb's Mill, near Kinston, by his own request he was allowed to join his company in the fight. At the close of the war he returned to his father's home, and remained there with him until 1869. During that year he entered the Kentucky University, where he received a literary and ministerial education, also reading dentistry during the five years he remained there. By his own industry he earned the necessary funds to pay his way through college by working as a painter and engaging in other mechanical pursuits, until he was finally graduated from that institution. He was afterward graduated from the dental department of the University of Tennessee.

For some time he traveled, practicing dentistry and preaching. He was at one time state evangelist for the Christian Church. In 1882 he located permanently in Kinston, N. C., where he continued in active practice until the time of his illness, which in one week terminated fatally.

Dr. Harper was well known as a dentist through the eastern part of the state and drew patronage from many counties. He stood in the front rank of his profession, and in 1894 he was elected president of the North Carolina State Dental Society without a dissenting vote, and presided in 1895 at the Salisbury meeting with great satisfaction to all its members.

Dr. Harper was a many-sided man, an example of the best type of citizenship, endowed by nature with a discriminating mind, a comprehensive grasp of human affairs, excellent judgment, an unflinching integrity, and above all, keenly developed human sympathies. His counsel was sought in all directions which tended toward the betterment of affairs in his community. His grasp of business methods and sound financial instincts were practically recognized in the demand for his co-operation in matters of this character. He was chairman of the County Board of Education for five years, and severed his connection with it during his last term by resignation. He was called to the command of the Naval Reserves when first organized in Kinston by the unanimous vote of the division. When practice forbade his longer service to the company, he was presented with his sword in recognition of his faithful and loving services. During the Spanish-American War he was appointed chaplain of the naval battalion of the state.

Dr. Harper was second vice-president of

the North State Mutual Life Insurance Company, director in several other corporations in Kinston, and also in the Chesterfield Mfg. Co. of Petersburg, Va. An appreciative biographer says of him, "Doubtless he was more universally liked in the community than any other; the rich, the poor, male and female, child and adult, all were his friends because he was theirs. His spirit of geniality and true Christian nobility, his kindly smile and warm heart, found a welcome everywhere at all times. He was the apostle of sunshine in this community; rare indeed were the times when the smile left his face."

Dr. Harper was fatally stricken while apparently in good health. He had gone a week previously to visit his second daughter, who was ill with typhoid fever at Wilson's Sanitarium. It was this illness which proved to be his last.

Dr. Harper married, April 21, 1877, Miss Delia Coward. His wife died in the spring of 1898, leaving six children to his guardianship.

SOCIETY NOTES AND ANNOUNCEMENTS.

[JAMESTOWN EXPOSITION, NORFOLK, VA., 1907.]

JAMESTOWN DENTAL CONVENTION,

TO BE HELD AT

Norfolk, Va., Sept. 10-12, 1907.

Committee of Organization.

BURTON LEE THORPE, St. Louis, Mo., *Chairman*.

H. WOOD CAMPBELL, Suffolk, Va., *Secretary*.

F. W. STIFF, Richmond, Va., *Treasurer*.

R. H. WALKER, Norfolk, Va.

THOS. P. HINMAN, Atlanta, Ga.

J. E. CHACE, Ocala, Fla.

CLARENCE J. GRIEVES, Baltimore, Md.

Exposition Company, the Southern Branch of the N. D. A., and the Virginia State Dental Association, will convene at Norfolk, Va., September 10 to 12, 1907. The Jamestown Exposition Company have appointed the above named gentlemen as a Committee on Organization, to elect officers in advance of the meeting, to appoint all committees, to finance the meeting, and to bring it to a successful termination.

The Committee on Organization have appointed Dr. Clarence J. Grieves, Baltimore, Md., general chairman of the Clinic Committee and Supervisor of Clinics.

A number of well-known men will assist him on the General Committee. State clinic chairmen have been selected from every state in the Union. The clinics are to be the principal feature of the convention, and it is expected to bring about the largest and most instructive dental clinics ever held. A surgical clinic will also be held under the supervision of Dr. L. M. Cowardin, Richmond, Va.

The Jamestown Dental Convention, to be held under the auspices of the Jamestown

The other members of this committee are J. Y. Crawford, Nashville, Tenn., and A. G. Friedrichs, New Orleans, La. Dr. F. W. Stiff, Richmond, Va., is general chairman of the Membership Committee.

Assistant state chairmen have been appointed from every state in the Union. Already membership fees are being sent in, and the promise is for the largest gathering of dentists ever held. Only five essays will be read at the convention, one by Prof. W. D. Miller, another by Prof. G. V. Black, and the other three by well-known southern dentists.

Several exhibits of much interest to the profession will be held under the auspices of the convention; among them the dental manufacture exhibit in charge of Dr. John W. Manning, chairman, Norfolk, Va.; a comparative anatomy exhibit, in charge of Dr. W. M. Bebb, chairman, Los Angeles, Cal., which exhibit will consist of three thousand comparative anatomy specimens, and also numerous other collections of interest; a dental historical exhibit, consisting of ancient instruments, operative and prosthetic work, books and photographs, under the chairmanship of Dr. Wm. H. Trueman, Philadelphia, Pa.; the orthodontia exhibit, showing a large collection of models, etc., under the chairmanship of Dr. H. E. Kelsey, Baltimore, Md. The U. S. Naval dental exhibit, showing 3000 charts of the mouths of midshipmen, under the chairmanship of Dr. John S. Marshall, San Francisco, Cal., will also show the equipment, method of keeping records, etc., used by the dental corps.

A full list of the various officers, who are to be elected in advance by the Committee on Organization at their next meeting in February 1907, and of the committees, will appear in due time in the various dental journals. The Committee of Organization is expected to select officers in advance in order that the officers may be prepared for their duties before the actual meeting of the convention.

A cordial invitation is extended to all reputable members of the profession to become members of this convention, and to assist the Committee on Organization in bringing about one of the best, if not the best, dental meeting ever held.

The Exposition itself offers an excellent opportunity for the busy practitioner to take a delightful vacation, see the wonderful his-

torical and naval and military exhibits at the Exposition, and also to participate in this meeting. The membership fee, which is \$5.00, should be sent to Dr. F. W. Stiff, treasurer, 600 East Grace st., Richmond, Va.

For further information address

H. W. CAMPBELL, Sec'y,
Suffolk, Va.

G. V. BLACK DENTAL CLUB CLINIC.

THE annual Midwinter Clinic of the G. V. Black Dental Club will be held at the Old Capitol building, St. Paul, Minn., on Tuesday and Wednesday, February 26 and 27, 1907.

The clinic committee has prepared the best program possible for it to arrange. The operative clinic and the list of essayists speak for themselves. The list of table clinicians has not been completed. Correspondence with exhibitors leads us to the belief that much which is new will be displayed for those coming from a distance.

Those who are interested in progressive dentistry are most cordially invited to attend our meeting, and take part in the discussion of the clinics and the ideas which will be presented by the essayists.

Special rates are given on all railroads. As there will be other conventions held in St. Paul at the same time, it is suggested that arrangements be made in advance for rooms. The Merchants Hotel and the Ryan Hotel have made a special rate for those attending the meeting. The secretary will gladly reserve rooms for all writing him.

TUESDAY, February 26th, 10 A.M.

Progressive clinic: Gold filling in mesio-occlusal surfaces of upper first molar and upper bicuspids.

1. Dr. A. C. Searl, Owatonna, Minn.
2. Dr. F. S. James, Winona, Minn.
3. Dr. J. W. S. Gallagher, Winona, Minn.

Dr. Wm. Finn, Cedar Rapids, Iowa, will demonstrate the entire method of procedure as followed by these clinicians, using for this purpose a large wooden tooth, clay, etc.

Progressive clinic: Gold filling in mesio-incisal surface of upper canine, lateral and central incisors.

4. Dr. G. N. Beemer, Mason City, Iowa.
5. Dr. W. R. Clack, Clear Lake, Iowa.

6. Dr. F. G. Richardson, Mason City, Iowa.
Dr. F. S. Robinson, Chippewa Falls, Wis., demonstrator.

Progressive clinic: Gold filling in mesial or distal surface of upper canine and lateral and central incisors.

7. Dr. S. Bond, Anoka, Minn.

8. Dr. A. C. Fawcett, Rochester, Minn.

9. Dr. C. H. Robinson, Wabasha, Minn.

Dr. A. M. Lewis, Austin, Minn., demonstrator.

10. Gold filling, occlusal surface of an upper or lower molar, demonstrating use of cohesive and non-cohesive gold. Dr. W. H. K. Moyer, Little Falls, Minn., demonstrator.

11. Porcelain demonstration. Dr. J. O. Wells, Minneapolis, Minn.

12. Amalgam demonstration. Dr. G. D. Moyer, Montevideo, Minn.

Afternoon, 2 P.M.

1st. President's Address. Dr. A. C. Searl.

2d. Report of Clinics.

3d. Essay, "Points of Contact, Their Use and Abuse," by Dr. W. H. K. Moyer.

4th. Essay, "Specific Gravity of Gold Filling," by Dr. K. E. Carlson. (Dr. Carlson will report the results of some experiments which he has made and is still making.)

Evening, 8 P.M.

Illustrated lecture by Dr. G. V. Black, Chicago, Ill.

WEDNESDAY, February 27th, 9 A.M.

The first three clinics are the same as those which will be made Tuesday morning.

Progressive clinic:

1. Dr. C. N. Booth, Cedar Rapids, Iowa.

2. Dr. Wm. Finn, Cedar Rapids, Iowa.

3. Dr. J. V. Conzett, Dubuque, Iowa.

Dr. J. W. S. Gallagher, demonstrator.

Progressive clinic:

4. Dr. J. J. Booth, Marion, Iowa.

5. Dr. T. F. Cooke, Burlington, Iowa.

6. Dr. W. G. Crandall, Spencer, Iowa.

Dr. F. S. James, demonstrator.

Progressive clinic:

7. Dr. S. R. Holden, Duluth, Minn.

8. Dr. A. M. Lewis, Austin, Minn.

9. Dr. F. S. Robinson, Chippewa Falls, Wis.

Dr. W. R. Clack, demonstrator.

10. Amalgam demonstration. Dr. J. B. Pherrin, Central City, Iowa.

11. Porcelain demonstration. Dr. F. S. Yaeger, St. Paul, Minn.

12. Gold inlay. Dr. C. E. Woodbury, Council Bluffs, Iowa.

Afternoon, 2 P.M.

1st. Report of Clinics.

2d. Essay, "The Relation of the Dentist to the Public and to His Patients," by Dr. T. F. Cooke, Mediapolis, Iowa.

3d. Essay, "The Treatment of the Teeth of Children," by Dr. C. N. Johnson, Chicago, Ill.

It is an impossibility to give a list of the table clinicians. A number of men have signified their intention to be with us, and give table demonstrations, which will be of the greatest value to all. This portion of the program has not been completed.

The secretary will be pleased to furnish any information necessary.

R. B. WILSON, Sec'y,

Am. Nat. Bank bldg., St. Paul, Minn.

BANQUET TO DR. G. V. BLACK.

THE Fraternal Dental Society and the St. Louis Society of Dental Science will unite in giving a banquet in honor of Dr. G. V. Black, at the Jefferson Hotel, St. Louis, Mo., on the evening of January 15, 1907. The afternoon of the same day Dr. Black will deliver an illustrated lecture on some phases of operative dentistry.

The long and untiring efforts and valuable scientific contributions of Dr. Black easily make him the foremost dental scientist the world has ever produced. No dentist, living or dead, so much deserves the thanks and praise of his professional associates. A most cordial invitation is extended to the members of the profession to be present at both lecture and banquet, and to assist in honoring Dr. Black. Those desiring reserved covers for banquet will remit \$5.00, the price per plate, to Dr. Richard Summa, secretary, Oriel bldg., St. Louis, before January 12th.

Committee—Geo. A. Bowman (chairman), A. H. Fuller, Edward H. Angle, D. O. M. LeCron, Adam Flickinger, Wm. Conrad, Burton Lee Thorpe. GEO. A. BOWMAN, Chairman.

AMERICAN DENTAL SOCIETY OF EUROPE.

THE American Dental Society of Europe will hold its next annual meeting in Rome, Italy, on March 29 and 30 and April 1. A very cordial invitation is extended to members of the profession to be present.

As it is the first meeting of the society in the Eternal City, it is hoped it may be the most enjoyable one in its history.

J. W. GALE, *Hon. Sec'y*,
79 Hohenzollern-Ring, Cologne (Rhine), Ger.

A CALL FOR AN INTERNATIONAL MASS MEETING OF DENTISTS.

THE "Open Letter" in the November journals has brought out responses having one purport, viz, showing a decided interest in the subject of preventive dentistry. From every point of the compass comes the unanimous concurrence in the opinion that it will be wise to issue the call. Therefore all dentists are invited to meet on Monday—the day previous to the annual meeting (January 15, 1907) of the New York Odontological Society at the Hotel Knickerbocker, Thirty-second st. and Broadway, at 9.30 A.M. Please respond in person or by correspondence. Address any of the names in "Open Letter," or

DR. G. ALDEN MILLS,
226 Central Park, West.

P. S. Original articles will be gladly received.

ALUMNI ASSOCIATION OF CHICAGO COLLEGE OF DENTAL SURGERY.

TWENTY-FIFTH ANNIVERSARY REUNION.

ON January 16 and 17, 1907, the Alumni Association of the Chicago College of Dental Surgery will celebrate the twenty-fifth anniversary of the establishment of the college by holding a grand reunion and clinic. Arrangements have been made for a number of papers, a very extensive clinic, a theater party, and a banquet. A railroad rate of a fare and a

third for the round trip from all points in the United States and Canada on the certificate plan has been arranged for.

A cordial invitation is extended to the general profession to be present, as well as all members of the Alumni Association, and all graduates of the college.

R. C. BROPHY,
J. P. BUCKLEY,
Committee on Publicity.

PENNSYLVANIA COLLEGE OF DENTAL SURGERY.

NOTICE TO THE ALUMNI.

ANY alumnus not having received a copy of the souvenir number of the *Pennsylvania Dental Times*, giving the proceedings of the golden anniversary of the Pennsylvania College of Dental Surgery, may secure the same by sending his name and address to

WILBUR F. LITCH, *Dean*,
Eleventh & Clinton sts., Philadelphia, Pa.

SOUTHERN NEBRASKA DENTAL SOCIETY.

THE second meeting of the Southern Nebraska Dental Society was held in Superior, Nebraska, November 13 and 14, 1906, in Dr. J. Frank Nelson's office; good attendance and a fine spirit. Several good clinics were given, also some fine papers by Dr. J. M. Prime of Oxford; Dr. N. H. Morrison, and Dr. E. A. Thomas of Red Cloud. Next meeting will be held in Superior in January.

W. A. MCHENRY, *Sec'y*.

OHIO STATE DENTAL SOCIETY.

AT the forty-first annual meeting of the Ohio State Dental Society, held in Columbus, December 4, 5, and 6, 1906, the following officers were elected: H. C. Brown, Columbus, president; C. I. Keely, first vice-president; W. H. Whitslar, second vice-president; Weston A. Price, treasurer. Board of Directors (for three years)—W. H. Todd, A. O. Rose, W. A. Barber, H. T. Smith.

F. R. CHAPMAN, *Sec'y*,
305 Schultz bldg., Columbus, Ohio.

ONTARIO DENTAL SOCIETY.

THE eighteenth annual meeting of the Ontario Dental Society will be held in the College Building, Toronto, Ont., February 25, 26, and 27, 1907.

A. E. WEBSTER, *Sec'y Program Committee*,
Toronto, Ont.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE forty-third annual convention of the Connecticut State Dental Association will be held at New London, Conn., April 16 and 17, 1907.

An excellent program is assured.

EDWARD S. ROSENBLUTH, *Sec'y*,
1051 Main st., Bridgeport, Conn.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

THE tenth annual session of the Southern California Dental Association will be held in Los Angeles, May 6, 7, and 8, 1907, at the same time that the Imperial Council of Mystic Shrine meets here, and all members of the dental profession contemplating visiting southern California at that time will confer a favor upon the association by notifying the secretary.

CHAS. M. BENBROOK,
455 S. Broadway, Los Angeles, Cal.

ARMY DENTAL CORPS.

CONTRACT Dental Surg. Hugh G. Voorhies will proceed to Fort William McKinley, Rizal, for duty, relieving Contract Dental Surg. George I. Gunckel, who will proceed to Camp Stotsenburg, Pampanga, for duty. Contract Dental Surg. George E. Stallman will proceed to Camp Wallace, Union, for duty. (Oct. 2, D. Luzon.)

Dental Surg. William H. Ware will proceed to Zamboanga, Mind., for duty. (Oct. 4, Phil. D.)

Dental Surg. George I. Gunckel, from duty in the Philippines, and will proceed on the first available transport sailing after Feb. 1, 1907, from Manila to San Francisco, Cal. (Nov. 30, W. D.)

Examining and Supervising Dental Surg. Robert T. Oliver, U. S. A., is detailed to represent the Medical Department of the Army at the meeting of the Executive Council of

the National Dental Association to be held in Washington, D. C., December 8, 1906. (Dec. 7, W. D.) Contract Dental Surg. F. Homer Wolven will remain on duty at Fort Monroe, Va., to February 1, 1907, upon which date he will proceed to Fort Hamilton, N. Y., for duty for a period of six weeks. (Dec. 10, W. D.)

A PUBLIC DENTAL LIBRARY

IN THE

City of Columbus, Ohio.

THE Trustees of the new Columbus Carnegie Library Building, a handsome structure costing \$250,000, have set apart a room 40 by 60 feet for the exclusive use of a Dental and Medical Library.

The local dentists have organized a Dental Library Association for the express purpose of bringing this matter to a successful issue, and the work thus far accomplished far exceeds our expectations. The Columbus dentists alone have donated \$500 in cash and a number of books and magazines.

To make this library complete in embracing all known works pertaining to our specialty and complete files of all the journals published, we desire the co-operation of every dentist in the state. Any old and rare works, copies of old journals, etc., will be gratefully received, inscribed with the name of the donor, and recorded to his credit in the library catalog. Please communicate with us concerning any literature you may have that you can donate to this cause, giving titles and authors of books; names and dates of journals, etc. In case of duplication they will be valuable for exchange with other libraries.

W. H. TODD, *Pres.*,
190 S. High st.
EDWARD C. MILLS, *Sec'y*,
10 Y. M. C. A. bldg.

INDIANA BOARD OF DENTAL EXAMINERS.

THE next regular meeting of the Indiana State Board of Dental Examiners will be held in rooms 11 and 12, State-house, Indianapolis, January 8 to 11, 1907. All applicants for registration will be examined at this time. For further information, blanks, etc., apply to

F. R. HENSHAW, *Sec'y*,
Middletown, Indiana.

DISTRICT OF COLUMBIA BOARD OF EXAMINERS.

THE Board of Dental Examiners of the District of Columbia will conduct the semi-annual examination at the Dental Department of Georgetown University, Wednesday, Thursday, and Friday, January 2, 3, and 4, 1907. All applications must be accompanied with a fee of ten dollars. For further information address

WILLIAM B. DALY, *Sec'y*,
1311 R. Island ave., N. W., Washington, D. C.

WISCONSIN BOARD OF DENTAL EXAMINERS.

THE next meeting of the Wisconsin State Board of Dental Examiners for examination of candidates for license to practice dentistry in Wisconsin will be held Monday, January 28, 1907, at the Hotel Pfister, Milwaukee, Wisconsin.

Application must be made to the secretary fifteen days before examination. The candidate must be a graduate of a reputable dental college, or have been engaged in the reputable practice of dentistry for four consecutive years, or an apprentice to a reputable dentist for five years.

For further particulars apply to

J. J. WRIGHT, *Sec'y*,
1218 Wells bldg., Milwaukee, Wis.

SOUTH DAKOTA BOARD OF DENTAL EXAMINERS.

THE next examination of the South Dakota State Board of Dental Examiners will be held at Sioux Falls, South Dakota, January 29, 30, and 31, 1907, beginning at 1.30 P.M. All candidates for examination must bring diplomas from reputable dental colleges or affidavit of having been engaged in the practice of dentistry for at least three years immediately preceding said examination. Instruments and materials necessary to do all kinds of operative and prosthetic work will be needed at this examination. Vulcanizer and lathe will be furnished by the board. All applications must positively be in the hands of the secretary by January 22d.

G. W. COLLINS, *Sec'y*,
Vermillion, S. D.

IOWA BOARD OF DENTAL EXAMINERS.

THE Iowa State Board of Dental Examiners will hold their next meeting for examination at Iowa City, February 6, 7, 8, and 9, 1907. Candidates will be furnished with proper blanks and such other information as is necessary upon application to the secretary. All applications must be filed with the secretary five days prior to the date of examination.

Address all communications to

E. D. BROWER, *Sec'y*, Le Mars, Iowa.

NATIONAL DENTAL ASSOCIATION.

COMMITTEE ON HISTORY OF DENTISTRY.

SOON after the Buffalo meeting of the National Dental Association in 1905, this committee announced, through the dental journals and otherwise, the exceptional opportunity which had made it possible to place before the dental profession a comprehensive history of dentistry from the earliest times down to the early days of the nineteenth century. Dr. Vincenzo Guerini of Naples, Italy, well known as a dental historian and archeologist, had placed at the disposition of the committee the result of his labors in the field of dental history, which has formed a large and important part of his life-work.

It was the desire of the distinguished author to bring out this book under the auspices of the National Dental Association as a material expression of his appreciation of the contributions which America had made to the progress of dentistry as a profession.

This tribute of the author was sympathetically received by the Committee on History of the N. D. A., not only because of its exceptional merit and the generous sympathy and appreciation which it expressed, but, further, because it furnished in available form and at once the result for which the committee had been created, and for which its members were individually and collectively laboring.

Upon recommendation of the Committee on History, the National Dental Association formally accepted this trust, and pledged its moral support to the enterprise of securing as soon as possible the publication of the work of Dr. Guerini. A thorough canvass of the

question from a business point of view disclosed the fact that without a definite, indeed guaranteed market for the book, no publisher could be found willing to undertake the assumed risk of financing the publication, and it was therefore determined by the committee to solicit subscriptions for the work, in order to assure the cost of its publication in advance. Accordingly, and based upon careful estimates, the price of subscription was placed at five dollars per copy, and it was found that not less than 700 copies would have to be subscribed for in advance, in order to guarantee the cost of publication.

By the aid of announcements in the journals, by personal solicitation, and direct appeal by circulars, etc., the present total number of subscriptions received by the treasurer is 400, leaving 300 yet to be obtained before the work of publication can be begun.

The committee asks that all who have not yet subscribed will do so at once. Surely there are enough men in our profession who are interested in its history, and willing to devote five dollars to the securing of such an historical record as has never heretofore been attempted. The matter is ready to put in type, and the book can and will be rapidly put

through the press just as soon as the amount necessary to accomplish that end is available for use by the committee.

Send your subscription without further delay to Dr. CHAS. S. BUTLER, treasurer, "The Frontenac," Buffalo, N. Y. Speak of the matter favorably to your colleagues and induce them to do likewise, so that this much-desired object may be consummated without any undue delay. The committee asks that the editors of all dental journals make note of this appeal, and thus lend their important aid to the cause which the committee hopes soon to bring to a successful issue for the benefit of the whole dental profession.

ORIGINAL COMMUNICATIONS.

EXPERIMENTS AND OBSERVATIONS ON THE WASTING OF TOOTH TISSUE VARIOUSLY DESIGNATED AS EROSION, ABRASION, CHEMICAL ABRASION, DENUDATION, ETC.

By W. D. MILLER, D.D.S., M.D., Ph.D., Sc.D., Berlin, Ger.

(Continued from page 23.)

(II.)

IN continuation of the investigations reported upon in the preceding issue of the Cosmos, I reproduce, first, in Fig. 16 a photomicrograph of washings obtained from prepared chalk, showing its rough character and the necessity, in the fabrication of tooth-powders, of using only chalk which has been very carefully prepared.

The same is true of powdered talc, which may contain as impurities gritty substances in varying amounts dependent upon the source of the stone and the care used in its preparation. The proportion of such impurities is naturally small, but it does not require much to make an impression upon the teeth in the course

of years. Fig. 17 shows the action of sediment from a tooth-paste containing talc upon a glass plate. The sediments obtained from many specimens of prepared chalk are quite as sharp. They may be tested by rubbing them on a glass plate with a strip of pink gutta-percha or with a bit of glass.* I wish also

*In this connection I wish to call attention to the sediment shown in Fig. 9 of the first section of this article (page 11, January Cosmos), and which I was at first inclined to think was powdered oyster-shell, but this was incorrect, as I find the residue to be due in a great part to impurities commonly present in the substance used in the manufacture of this paste. The large particles in

to call attention to Figs. 18-20, which show the striking results sometimes obtained by the simple use of the brush and powder, and throw some light upon puzzling cases occasionally met with in practice.

In Fig. 18 the effect is shown of brushing four teeth from different dentures

show large wedge-shaped defects at the necks extending to different distances upon the facial surfaces. The difference in the action upon the bicuspid and its neighboring incisor is surprising, particularly to the casual observer, to whom the surface of the enamel of the incisor seems to have suffered no change at all,

FIG. 16.

Washings from prepared chalk.

for 5 hours with calcium carbonate and 18 hours with 20 per cent. pumice added. No. 1 is a sound central incisor almost colorless, having but a trace of gray in it. No. 2 is a dark gray senile bicuspid. Nos. 3 and 4 are molars, No. 3 inclining to the gray type while No. 4 is distinctly white. We see that the bicuspid has lost the whole of its enamel and a considerable part of the dentin, and that its surface is scored by numerous parallel grooves. The other teeth

although a careful examination will show that the enamel plate is very thin and is on the point of breaking through on the margin next to the bicuspid. The enamel on No. 4 is also as thin as paper, so that the difference in the action upon the different teeth is not so great as it appears.

Fig. 19 is a deciduous tooth brushed with a gritty tooth-powder. It shows a fairly deep wedge-shaped defect at the neck and two circumscribed deep defects of the enamel separated from each other by a bridge. It is sometimes difficult to understand why certain spots are picked out, but such is the case. It may be accounted for in part by the

Fig. 6 are equivalent to large crystalline bodies which I have found in certain preparations of precipitated chalk.—W. D. M.

presence of weak spots in the enamel and in part by the particular direction given to the bristles by the configuration of the neighboring teeth or gums. Then, again, the whole surface of the enamel may be worn down until it breaks through at some particular more prominent spot; then, the dentin being exposed,

more energetically than is the case in the mouth. In those experiments in which a strip of pink gutta-percha was fixed parallel with the alveolar border, the bristles, being prevented from spreading out freely on the corresponding side, cut especially deep.

Then again, on brushing the facial sur-

FIG. 17

Action of sediment from a tooth-paste containing talc, on glass.

the abrasion extends rapidly from that particular point, and considerable progress may be made in a comparatively short time. In the present case the enamel is much thinned down over the whole surface of the tooth.

In my experiments I have found a greater tendency toward the cutting by the brush into the neck of the teeth than we find usually in the mouth in severe cases of erosion. This may be due in part, I think, to the fact that only one row of teeth is brushed at a time, and there being no sensitive gums to ward off the brush as well as no gums to protect the necks of the teeth, they are rubbed

faces of our teeth we naturally close or very nearly close the mouth and brush both rows at the same time. The bristles spread out on the surfaces of the teeth and only the very outside rows reach the necks of the teeth. Or again, if the mouth is not completely closed, so that a space remains between the two rows of front teeth, the bristles working in this space may wear away the cutting edges and cause a certain amount of shortening of the teeth. This is imitated in an experiment in which a bar of wood was placed opposite the cutting edges of the lower front teeth at a distance of from 2 to 3 mm. from them. The effect of

brushing for eighteen hours with an English tooth-paste was to shorten the teeth, as seen in Fig. 20. They also show considerable wearing at the neck, and

powder. My views on this question will be given later.

FIG. 20.

Shortening of the teeth by the action of brush; also longitudinal defect in the right lateral produced by brushing horizontally. In the right central the defects produced at the neck and on the cutting edge are joined by a longitudinal groove.

FIG. 18.

Selective action of brush on one particular tooth.

almost total destruction of the enamel of No. 1, which is worn away in a very irregular manner. In the other incisors the enamel is also very much worn down,

FIG. 19.

Localized penetrating action of brush.

and the dentin is beginning to appear in No. 4 toward the neck.

About 2½ boxes of tooth-paste were used in producing this result—a quantity which I judge many patients use up in one year or possibly much less time.

Notwithstanding these pronounced and diversified results produced by the action of the brush and powder on the teeth, I am free to confess that, in some cases which I have seen, the action of an acid or other chemical body as predisposing cause, rendering the tissue more susceptible to friction, would facilitate the explanation.

It must not be inferred from the above that I discountenance the use of the tooth-brush or a proper use of a proper

II. CHEMICAL SUBSTANCES WHICH ATTACK THE INORGANIC CONSTITUENTS OF THE DENTIN AND ENAMEL AS A CAUSE OF WASTING.

It is practically only acids and acid salts that we have to deal with here. The fact is too well known to require particular emphasis that dilute solutions of organic as well as of inorganic acids and acid compounds have a pronounced action upon the hard tissues of the teeth. In the case of the enamel the appearance presented under the microscope has led to the supposition that the acid dissolves the cementing substance between the enamel prisms, thereby permitting them to fall apart, pretty much as the bricks in a wall from which the mortar has been dissolved out. It is a question, however, whether the breaking up of the enamel is not due rather to a solution of the cortical layers of the enamel prisms by the acid. In the case of the cement and dentin a veritable decalcification takes place, the calcium salts being extracted by the acids, which leave the organic basis sub-

stance but slightly altered. Whether and to what extent the acid forms a new compound with the calcium salts of the tooth tissue or simply holds them in solution is a question deserving of much more thorough study than it has heretofore received. It is too complicated to be dealt with here and will be taken up on another occasion. Suffice it to say that different acids act with very varying degrees of intensity upon the tissue of the tooth—from nitric, hydrochloric, lactic, etc., which even in dilute 1 per cent. solutions speedily decalcify the tissue, to thymic, carbolic, and many other acids whose action is very slight or practically nil.

Accordingly, it must not be supposed that every substance that contains acid properties is destructive of tooth tissue. Some acids form soluble and others insoluble compounds which may be precipitated upon the surface of the tooth or in its superficial layers. Sometimes the calcium salts extracted from the dentin are re-precipitated upon its surface. Of particular importance in this connection is the comparative rapidity with which different acids act upon dentin and enamel. If we suspend a tooth in a solution of hydrochloric, acetic, nitric, lactic, or phosphoric acid, or in acid sodium phosphate, we will find that the dentin is decalcified much more rapidly than the enamel. In oxalic acid, on the other hand, as well as in tartaric, mucic, and probably some others, the enamel is acted upon as much as or even more intensely than the dentin, a result which should not be lost sight of in an attempt to determine the part which acids may have in the production of wasting.

Very surprising results are obtained by the action of oxalic acid upon the teeth. A tooth suspended in a 1 or 2 per cent. solution of this substance will become studded in a few days with numerous hollow spherules from 0.5 to 4 mm. in diameter. They are white, semi-transparent and respond to the test for calcium oxalate. The enamel of the tooth is attacked in a very striking manner, being dissolved in pits and channels looking very much as if worm-eaten. (Fig.

21.) The dentin is much less affected than the enamel. So, too, a tooth split into halves and left for four weeks in grape-juice, with the split surface up, be-

FIG. 21.

Strange effect of a 1 per cent. solution of oxalic acid on the enamel.

came coated with crystals, whether tartrates or phosphates was not determined. In this case, too, the action upon the dentin was much less pronounced than upon the enamel. (Fig. 22.)

ACTION OF VAPORS OF POWERFUL ACIDS.

All acids, as far as we know, in acting upon enamel and dentin leave a rough unpolished surface, and no one as yet has been able to produce anything which could be mistaken for wasting by the action of acids alone.

We occasionally meet with the statement made by some author that he has produced erosion by subjecting a tooth to the action of some acid. Usually neither the strength of the acid nor the length of time during which the tooth was exposed to it have been given, so that it is not possible to verify such reports. After having examined over a dozen different acids and acid salts in various concentrations I am convinced that such reports are to be accounted for on the supposition that the author has not given the tooth a sufficiently careful examination. The nearest approach to the production of wasting by acids alone is found in the results which I have obtained by the action of the vapors of powerful acids or acid mixtures (strong nitric acid, nitro-

hydrochloric acid, or a mixture of nitric and sulfuric acids).

At the first annual meeting of the Standesverein Berliner Zahnärzte, Professor Levin reported a case of severe erosion observed on the teeth of workmen in dynamite manufactories. A greater part of the crowns of the lower incisors

contact with the tooth, both dentin and enamel, *not only the inorganic but the organic portions as well*, were so completely disintegrated that in rubbing over the surface but slightly with a soft tooth-brush the tissue was brushed away, leaving a hard polished surface. The wasting in this case is practically equivalent

FIG. 22.

Stronger action of grape-juice on enamel (a) compared with dentin (b).
Black lines denote decalcified tissue.

in particular and the cutting edges of the upper incisors were destroyed, and the defects had a perfectly smooth polished surface. The case appeared very puzzling to me until it became clear by the following experiment: A small quantity of a mixture of about equal parts of sulfuric and nitric acids, which is used in the manufacture of dynamite, was put into a flask, and a tooth was suspended above the liquid by means of a platinum wire. The liquid was renewed every day, the tooth being inclosed in a rubber tube containing a small hole at one point so as to expose a limited portion of dentin and enamel. Where the fumes came into

to erosion, as only a minimum of mechanical action is necessary to produce the smooth surface. The eroding body is nitrogen peroxid (N_2O_4), and the same effect may undoubtedly be obtained by exposing teeth to the action of the fumes of fuming nitric acid alone, which also gives off N_2O_4 . A similar result is produced by the vapors (chlorin) given off by nitro-hydrochloric acid.

In a conversation with Dr. Davenport of Paris on the subject of wasting of the teeth, he referred me to a communication published by him in the Transactions of the American Dental Association, 1881. This communication shows

that he had made the clinical observations reported by Levin twenty-six years ago. In Davenport's case the upper central incisors were worn away one-half their length, the laterals to a less extent, and the canines a very little; the other teeth were not affected. Thus a wide space was left between the upper and lower incisors when the teeth were closed. No teeth could be seen during conversation, as they were worn away even with the line of the lips. The lower teeth, being completely covered, were not affected.

Up to eight years prior the patient had lived upon a farm, and at that time his teeth were perfect. He then engaged as a workman in the manufacture of nitric acid and oil of vitriol, when, to use his own expression, "The gases escaping from the retorts set my teeth on edge, and I soon noticed that they were wearing away."

He also stated that the teeth of all the other workmen were more or less affected, according to the extent that they were left uncovered by the lips; in some both the upper and lower teeth were involved.

The patient stated that the entire wearing away of his teeth had been accomplished within six months after his entering the factory.

It is not necessary to emphasize the fact that factors of this nature do not come into consideration in ordinary cases of wasting.

ACTION OF CARBONIC ACID ON THE TEETH.

It is a well-known fact that carbonic acid is a powerful solvent for the calcium salts. Its action is easily demonstrated by putting sections of teeth or halved teeth in a bottle of water charged with carbonic acid. The dentin becomes decalcified to a considerable depth, and the enamel surface white and chalky in a few (two to four) weeks.

Inasmuch, now, as human saliva contains carbonic acid in solution, and carbonic acid is constantly being exhaled with the breath, it becomes a question demanding attention whether the CO_2

may not under certain circumstances have a deleterious effect upon the teeth. My attention was called to this matter by a case of mouth-breathing in which there was a wasting away of the enamel from the lingual surface of the upper incisors, and to a slight extent of the canines. The overbite was pronounced, and undoubtedly some of the wearing was simply due to attrition; but still I was not quite satisfied that this was the sole cause, particularly as the surfaces lacked in some parts the smooth polish present in attrition. As I could find no other apparent cause, especially no pronounced acid secretions, the thought suggested itself to me that possibly the current of exhaled air laden with CO_2 (in the expired air of human beings Vierordt, "Physiologie des Athems," found 4.6 to 5.2 per cent. of carbonic acid), impinging upon the surfaces of the upper incisors—the lower would be protected by the tongue—might have something to do with the wasting. For myself, I am not at all convinced that such is actually the case, and naturally the question arises, Why do not all mouth-breathers show the same phenomenon?

Nevertheless it appears to me that the matter is deserving of further attention. On the other hand, I think it may be considered as fairly certain that the CO_2 in the saliva does not have any detrimental effect on the teeth, as we should expect to find any such effect at the points where the saliva is poured into the mouth. The saliva of dogs, moreover, contains more free CO_2 than human saliva—namely, 19.3 to 22.5 volume per cent., and yet it does not appear to have any detrimental effect upon their teeth. An experiment in which a current of carbonic acid is made to impinge upon the surface of a tooth is now in progress, and will be reported upon in a subsequent issue.

The question has been brought up as to whether solutions of acids in water act differently from the same solutions in saliva. I have only one experiment to report on this question. Teeth were halved, and the corresponding halves subjected to a semi-saturated

solution of acid calcium phosphate in water and in saliva respectively for thirty-four days. The action of the watery solution seemed to be more intense than that of the solution in saliva. The temperature of the solutions is certainly not without influence, and I have therefore carried out my experiments as far as possible in the incubator.

ACTIONS OF ACID SOLUTIONS IN MOTION.

Very interesting intensified effects were produced by the action of acids in motion. Dropping, running, or trickling over the teeth in capillary currents, they cut grooves in the enamel with astonishing rapidity.

A fine stream of lactic acid 1 per cent., falling two and one-half feet on a block of ivory, produced rapid decalcification but no loss of substance. The surface was dull. A row of six teeth was fixed in plaster of Paris, and set on end with a fine stream of a 2 per cent. solution of phosphoric acid striking the surface of the upper teeth and trickling down over the others. The enamel of all the teeth was more or less cut and grooved in 60 hours. That of the upper two was totally destroyed, the dentin was exposed and superficially decalcified but not worn; the surface was dull.

A fine stream of a 1 per cent. solution of lactic acid, striking the third molar of a mandible and trickling down over the other teeth, produced a similar and nearly as intense an action in 50 hours.

The left side of the same jaw was exposed to a stream of a 1 per cent. solution of sulfuric acid for 25 hours (Fig. 23). The action was intense, nearly all of the teeth being denuded of their enamel, and the dentin softened, but with no loss of substance, the surface not being polished.

A single molar was exposed for 60 hours to a fine stream of acid calcium phosphate, 1 per cent. solution. The surface upon which the liquid impinged was denuded of enamel, and the dentin softened; a groove was also cut around the neck of the tooth. The acid sodium phosphate in the same strength had but a very slight effect.

Three capillary glass tubes were attached to the left maxilla in such a way that their points rested upon the buccal surface of the molars near the neck. Four silk threads were likewise fixed to the bone with sealing-wax, and by means of wax balls attached to the

ends were drawn down over the surfaces of the bicuspid, canines, and lateral incisors. The upper ends of the glass tubes, as well as of the threads, opened into a receptacle

FIG. 23.

Action of a running 1 per cent. solution of sulfuric acid. Teeth almost entirely divested of enamel.

constructed of a plate of wax. A 1 per cent. solution of phosphoric acid was introduced into this receptacle drop by drop, and worked its way through the capillary tubes and along the silk threads to and along the surfaces of the teeth. In the course of eight days deep undermining grooves were cut in the enamel, these in the case of the molars exposing the dentin.

In all of these experiments the result was simply decalcification, and in none was any effect resembling wasting produced. It seemed to me, nevertheless, to lie quite within the bounds of possibility that certain rare effects seen in the mouth may owe their origin in part to some action of this kind. Undoubtedly, currents of saliva are forced between or along the teeth in certain lines in chewing, and when the saliva or the food is acid, an effect might be brought about in time. I have seen the distal surface of an upper first bicuspid, where the second bicuspid was wanting, grooved out in very much the same way as the teeth are grooved in my experiments, and the thought has suggested itself to me whether this action might not in part have been brought about by acid secretions trickling down the channel formed by the tooth, the cheek, and the tongue. Moreover, it would not be at all surprising to me if a man who was in the habit of drinking acid wine and drawing it

through his teeth, as some do, should in time wear away the enamel from the approximal surfaces of his front teeth.

A section of the mandible containing three teeth was fixed with wax in a glass tube fourteen inches long, at right angles to the tube, which was then closed at one end and one-quarter filled with an acid brand of Rhine wine. The other end now being closed, the tube was rotated end over end during 48½ hours, the wine being occasionally renewed. A very considerable decalcification of the enamel was produced.

In all of these cases, however, the smooth polish is wanting, and when the surface of the dentin is reached it becomes decalcified (softened) but does not wear away, so that we must also admit that even with acid solutions in motion we are not able to produce wasting.

III. ACTION OF ACIDS OR ACID SALTS IN COMBINATION WITH MECHANICAL ACTION.

We have seen that it is quite possible to produce effects upon the enamel and dentin which are identical in appearance with wasting, by the use of the tooth-brush with tooth-powder, and on the other hand that it is quite impossible, so far as our present experience goes, to produce these effects by the application of any acid or acid compounds which are found in the mouth. The question now arises, What is the effect upon the teeth of the combined action of acids and of mechanical agents?

To bring about as decisive a solution of this question as possible, no time or pains were spared to carry out the required experiments, and to repeat them as often as necessary to secure reliable results. Some of the experiments are given here in detail, in order that each one may make his own study of them, and judge if I am right in my conclusions. In these experiments, human teeth and occasionally blocks of ivory were suspended in various acid solutions in different concentrations, and at specified times were removed and brushed with various different tooth-powders, or

constituents of tooth-powders. In some experiments whole teeth were used; in others, sections of teeth. In many cases the teeth were protected against the action of the acid by a coating of paraffin or sealing-wax, or by being inclosed in a rubber tube with a window cut so as to expose the dentin and enamel at one point.

In most of my experiments, however, sections of the human jaw with a number of teeth were used, or the teeth were fixed in rows in plaster of Paris or sealing-wax, which is much better for the purpose, and the facial surface covered with a thin layer of cotton, which was then moistened with the solution to be experimented with. This arrangement seemed to me to present the greatest similarity to the conditions in the mouth, the layer of cotton representing the mucous membrane of the lips or cheeks. In one case a human jaw was fixed in plaster of Paris, and a sheet of rubber dam so attached as to represent the cheek, thereby producing a natural interference in the application of the brush. In many cases the teeth, before beginning the experiment, were filled with gold, amalgam, or gutta-percha, and very valuable data were obtained from the comparative comportment of the different materials under the action of the acid and the brush.

Experiment 1. A block of ivory was suspended in a 1 per cent. solution of lactic acid so that one-half of it was immersed. It was daily removed and brushed with 10 per cent. pumice. The immersed (decalcified) half wore away much less rapidly than the other half. The result was the same whether a soft brush with 10 per cent. pumice, or hard brush with pure pumice, or even with corundum powder was used; only, when a wire brush was used the decalcified dentin was torn away much more readily.

Experiment 2. A number of carious teeth were halved and brushed with 15 per cent. pumice. The normal dentin wore away much more readily than the carious. This experiment was frequently repeated, always with the same result.

Experiment 3. A number of halved teeth were suspended in a solution of acid calcium phosphate, removed daily and brushed with 10 per cent. pumice. In many months the

enamel margins were destroyed, and the dentin, which was softened (decalcified) to a depth of over 1 mm., stood up above the enamel and showed no loss of substance. With the acid sodium phosphate the result was the same. (Fig. 24.) This experiment was continued for thirteen and one-half months; for the first two months with 1 per cent., then with 5 per cent. of acid sodium phosphate, and brushed daily with chalk. The mechanical action is here too slight in com-

powder. There was distinct loss of substance, with polished surface on both sides of the decalcified spot, which was comparatively but slightly affected and remained unpolished.

Polished surfaces of ivory subjected to the action of weak acids (1 per cent.) lose their polish in fifteen to thirty minutes. Human dentin gives up its polish much less readily.

FIG. 24.

Section of tooth exposed for two months to 1 per cent., and eleven and one-half months to 5 per cent. acid sodium phosphate, brushed daily on surface (a). Black portion denotes decalcified tissue.

parison with the chemical. By sufficiently increasing the brushing and reducing the strength of the acid we may obtain different results.

Experiment 4. A spot 3 mm. in diameter at the neck of a bicuspid was superficially decalcified by a 1 per cent. solution of lactic acid, and the tooth so fixed in a glass tube containing powdered corundum in water, that when the tube rotated, the mixture flowed back and forward over the surface of the tooth. In a week the non-decalcified surface showed a slight wearing away, which was absent at the spot decalcified. This experiment was repeated using brush and

Experiment 5. Fermented bouillon was applied on cotton to the teeth of the left side of a mandible, and both sides brushed daily for about ten seconds each with prepared chalk during one year and one month. The necks of the teeth on the right side showed slight action of the brush and a high polish, while on the left side there was more the appearance of beginning superficial caries.

Experiment 6. Five teeth, one having an amalgam and another a gold filling, were set in plaster of Paris, treated with 10 per cent. hydrochloric acid applied on cotton for ten minutes, then brushed for five minutes with pumice. This process was repeated four times, with the result that shallow grooves

were produced at the necks of the teeth, and the enamel plates thinned down, *so that both of the fillings stood high above the surface*: fillings. dentin. and enamel having a fair polish.

Experiment 7. Four teeth were ground down from the approximal surface so as to expose the dentin; two of them were subjected to the action of pumice in water, the other two to the action of pumice in a 10 per cent. solution of hydrochloric acid on the motor brush for the same length of time. The former showed a cupping of the surface of the dentin, the enamel margins standing higher, and also a gold filling in the fissure wearing down equally with the enamel. In the latter just the opposite condition was produced, the enamel wearing down much more rapidly, the dentin and an amalgam filling standing high above the surface of the enamel.

Experiment 8. The same experiment was repeated, with the addition of two small blocks of ivory in each case. The same conditions resulted in the teeth, while the blocks of ivory subjected to the action of the pumice in water showed much more wearing than did those with pumice in the 10 per cent. solution of hydrochloric acid.

Experiment 9. Five teeth—canine, two bicuspids, and two molars—numbered 1 to 5.

FIG. 25.

Action of 10 per cent. hydrochloric acid in conjunction with friction.

under the action of 10 per cent. hydrochloric acid on cotton for $9\frac{1}{2}$ hours, brushed every half-hour for five minutes with an English tooth-paste, then under 10 per cent. phosphoric acid for 23 hours, brushed half-hourly for seven minutes. Nos. 3, 4, and 5 are cut deeply, opening the pulp-chamber; Nos. 1 and 2 being less affected. The destruction in the case of the first molar involves the whole buccal surface and part of the morsal surface; in the other teeth the amount of wearing is in the order 4, 3, 5, 2, 1. All are highly polished. (Fig. 25.)

Experiment 10. Three teeth, numbered 1, 2, 3. No. 2, with a gold filling, was subjected to a 10 per cent. solution of hydrochloric acid on cotton for $7\frac{1}{2}$ hours, and brushed every quarter hour for five minutes with pumice; then for $9\frac{1}{2}$ hours and brushed every one-quarter hour for two minutes. Preponderance of mechanical action. The pulp-chambers are opened by large wedge-shaped incisions which extend on the buccal surface half-way to the morsal margin. The gold filling was polished and rounded off at the edges, but still slightly *higher than the surface of the enamel* (evidence of acid action). All surfaces are fairly polished.

Experiment 11. Two teeth, molar and canine, were treated for 17 days with 2 per cent. solution of oxalic acid and brushed twice daily one-half minute with pumice; then for $55\frac{1}{2}$ hours with 5 per cent., brushed for three-quarters of a minute quarter-hourly; then for 18 hours brushed three-quarters of a minute half-hourly. The molar has a wedge-shaped defect at the neck involving half of the buccal surface, while the enamel on the labial surface of the canine is totally destroyed and a strikingly typical cavity formed. This cavity developed very rapidly during the last three days. The margins of the canine especially are sharp, and the dentin is deeply hollowed out. Both cavities have a high polish. (Fig. 26.)

Experiment 12. Five teeth in plaster, one with a gold filling, bathed for 8 hours with 1 per cent. hydrochloric acid on cotton, brushed hourly for five minutes with 5 per cent. pumice, then for 13 hours brushed two minutes hourly, then for $18\frac{1}{2}$ hours brushed

FIG. 26.

Action of oxalic acid in conjunction with friction.

two minutes half-hourly and for 78 hours one minute half-hourly. Extensive defects were produced at the necks and extending upon the enamel surfaces, in one case following along the disto-labial margin of an incisor to the cutting edge, giving a perfect and beautiful reproduction of a typical case of wasting. The gold filling was evidently worn, but was standing higher than the surface of

the dentin (mechanical action). All surfaces are well polished. The enamel shows characteristic markings; the margins of defects are fairly sharp.

Experiment 13. Four teeth bathed in the manner described in a 5 per cent. solution of tartaric acid on cotton for 37 days, brushed the first 28 days four times daily for one minute, for the remaining days five times daily. The margins of the cavities are sharp, and the surface highly polished. Close examination will also show that the enamel plate has been considerably thinned down.

Experiment 14. Four teeth numbered 1, 2, 3, 4, treated for 11 days with 5 per cent. citric acid and brushed four times daily for one minute with an English tooth-paste, then for 19 days with 1 per cent. and brushed twice daily. Bright shallow facets are present at the necks of all of the teeth, reaching in No. 2 half-way to the margin of the morsal surface; in Nos. 1, 3 and 4 they are less extended. The margins are sharp, the surface of the enamel perfectly smooth and bright in No. 3, but slightly roughened and showing chalky streaks in Nos. 1, 2, and 4. The enamel striæ are distinctly visible in Nos. 1, 2, and 4, indistinctly in No. 3.

Experiment 15. Four teeth, numbered 1 (canine), 2 (bicuspid), 3, 4 (molars)—No. 3 filled with gold—were treated with 5 per cent. hydrochloric acid for 9½ hours, brushed half-hourly for five minutes, for 11 hours hourly for two minutes, for 41 hours half-hourly two minutes, with pumice. The cavities are all shallower than those produced by the same application of the brush without acid; they are well polished, with fair margins. In No. 1 the cavity is divided by two diverging ridges into three sections. The polished enamel shows no evidence of wear, yet it has been worn down very considerably and the gold filling stands at least ¼ mm. higher than the surface of the enamel (unmistakable evidence of acid action). The enamel striæ are faint.

Experiment 16. Four teeth numbered 1 (bicuspid), 2 (canine), 3 (molar), 4 (canine), treated with 5 per cent. oxalic acid for 32 hours, brushed quarter-hourly for ten seconds with 10 per cent. pumice, then for 47½ hours brushed quarter-hourly for twenty-five seconds, and for 7 hours brushed quarter-hourly for forty-five seconds. Comparatively shallow extensive cavities were produced, involving in Nos. 1 and 3 nearly the whole of the buccal surface. The surface of the cavities is traversed by numerous ridges. Margins are not very sharp; there is a distinct wearing down of the remaining enamel; the

surface is fairly polished, but under the magnifier presents a pitted appearance, with striæ faint or invisible.

Experiment 17. Six teeth—central, lateral, canine, bicuspid, first and second molars—placed in a curve to reproduce the natural arch, were bathed with 5 per cent. phosphoric acid for 13 hours, brushed hourly for two minutes with 50 per cent. pumice; then for 11 hours brushed hourly three minutes.

FIG. 27.

Beautiful case of wasting (chemico-abrasion) produced by the action of phosphoric acid in conjunction with friction applied horizontally; 3. gold; 4. gutta-percha filling.

and for 73 hours four minutes hourly. In No. 1 is seen a beautiful case of wasting, beginning at the neck and extending along the disto-labial margin to the cutting edge (Fig. 27), and then spreading laterally. No. 3 was filled with gold, No. 4 with gutta-percha at the neck. Both of the fillings stand higher than the surrounding dentin. The enamel of all the teeth is very thin; the polish fair, that of the dentin high. The cavities at the neck are not so deep as would be produced in the same time without the action of acid. Striæ are distinctly visible under glass. Duration of experiment 97 hours; total amount of brushing 6 hours.

Experiment 18. The teeth of the right half of a mandible were treated separately from the third molar forward with 5 per cent. solutions of hydrochloric, phosphoric, oxalic, lactic, and sulfuric acids, and water, all brushed alike with 10 per cent. pumice powder for one minute half-hourly. In 19 days the enamel of No. 1 was completely destroyed, the dentin being softened to a depth of 1 mm. or more, but with no wearing. Nos. 2 and 3 have shallow, brightly polished cavities at the neck and extending upon the enamel about half-way to the morsal margin. The enamel surface is polished, but presents a pitted appearance and is considerably worn down. No. 4 presents similar changes except

that the pitted appearance of the enamel is wanting and there is a soft (decalcified) spot in the center of the cavity, where the wearing away is evidently being retarded. No. 5 is similar to No. 4, but shows only a trace of softening at two very small points. In No. 6, treated with water, the enamel is but very slightly affected, the highly polished cavity being restricted to the neck of the tooth.

Experiments 19-22. Twenty teeth were mounted in plaster of Paris in four rows of five teeth each. In the first row (experiment 19) the teeth were treated separately, No. 1 with 10 per cent., No. 2 with 5 per cent., No. 3 with 2 per cent., No. 4 with 1 per cent. hydrochloric acid, and No. 5 with water. All were brushed alike for one minute half-hourly with a rubber brush without powder. In 16 days the enamel plate of No. 1 was completely gone, the dentin softened, and a filling of amalgam projected above the surface by the thickness of the enamel. No. 2: Filling of phosphate cement partially washed out, cervical portion of enamel gone and dentin

FIG. 28.

[Described in text.]

softened; the remaining portion has a chalky surface. No. 3: Same changes in less degree, the gold filling projecting above the surface of the enamel. In No. 4 the enamel is nowhere broken through; it has, however, been reduced in thickness, the filling of gutta-percha standing higher than the surface of the tooth. The enamel has a slight polish in the central parts, surrounded by chalky margins. No. 5 shows no change. In the second row (experiment 20) the arrangement was the same, except that phosphoric acid was used instead of hydrochloric, and the teeth were brushed with a soft bristle brush with 10 per cent. pumice. The teeth were filled, in order, with gold, gutta-percha, gold, amalgam, and cement. The action of the acid is less and that of the brush more pronounced throughout.

After 16 days we find the enamel plate of No. 1 destroyed and the dentin decalcified. There is considerable loss of substance at the neck of the tooth notwithstanding the decalcification. In Nos. 2 and 3 we have a mixture of decalcification and abrasion, in No. 4 almost pure abrasion, there being only a small spot of softened dentin on the margin of the filling. From this we see that under the action of a 1 per cent. solution of phosphoric acid a tooth must be brushed for at least one minute half-hourly with 10 per cent. pumice to maintain a polished surface. In No. 5 we have pure abrasion. The enamel surface in No. 2 lacks the normal polish. Nos. 3 and 4 are fairly, and No. 5 highly polished. (Fig. 28.)

In the third row (experiment 21) the disposition was just the same as in the second. The teeth were filled with cement, gold, gutta-percha, amalgam, and gold in succession, and brushed half-hourly for two minutes with a hard brush with 10 per cent. pumice. In No. 1 two-thirds of the enamel plate is destroyed and the underlying dentin softened; no apparent wear except at the neck. In Nos. 2 and 3 the teeth are badly cut, but, in both, traces of soft dentin are present; the enamel surfaces lack their normal polish; the fillings stand slightly above the enamel surface (a sure sign of excessive chemical action). In No. 4 we have the appearance of pure abrasion; the surfaces are highly polished, and the amalgam is worn down below the level of the enamel. In No. 5 the wear is most intense and the gold lies slightly lower than the surface of the enamel. In No. 4 a narrow groove is worn between the filling and the enamel margin. In No. 5 this groove is wanting.

In the fourth row (experiment 22) the teeth—filled with gutta-percha, gold, amalgam, amalgam, gold—were treated respectively with phosphoric acid of 5, 3, 2, and 1 per cent. and water, and brushed half-hourly for two minutes with a hard brush and pure pumice. Here the mechanical action predominates, and the cutting at the neck increases from No. 1 to No. 5. A narrow zone of enamel around the filling in No. 1 is destroyed and the dentin decalcified; the enamel surface shows the action of the acid. In No. 2 the filling has fallen out, in Nos. 3 and 4 the fillings lie far below the surface of the enamel (denoting the preponderance of mechanical action), and slightly above that of the dentin. The enamel of Nos. 2, 3, and 4 is fairly polished, but lacks the brilliancy of No. 5. The gold in No. 5 is slightly lower than the enamel surface. In nearly all of the experiments the enamel striæ are more distinct in the teeth acted upon by acid. This is, however,

not always the case, and can therefore not be made use of as a means of diagnosis.

Experiment 23. Two teeth suspended by a string in a concentrated solution of mucic acid, brushed twice daily for 6 weeks, (a) with 10 per cent. pumice, (b) without powder. A slight loss of substance was produced at the necks of both teeth, especially a. Enamel surface of a is pitted, that of b smooth.

These, and many other experiments not here recorded (over two hundred in all were made), confirm the conclusion arrived at under division II, that acids alone can never produce wasting. On the other hand, however, wasting of the enamel is materially accelerated by the action of acids, and I had no difficulty in producing cases as typical as any which may be met with in the human mouth. It is only requisite that the mechanical action be in a definite ratio to the chemical, otherwise we get a rough surface with whitish chalky margins on drying, and the typical character is wanting. In the case of the dentin the results were different, and it appears here that nothing is gained by the action of the acid. Experiments on ivory, as well as on human dentin, repeated time and again, have shown that dentin which has been decalcified by the action of an acid is less susceptible to wear under the brush than normal dentin. This result does not surprise us, since we know very well that brittle substances grind away more rapidly than soft tough ones. We might grind for hours on a piece of rubber tubing without grinding it away to any great extent, and every dental histologist knows that carious (decalcified) dentin resists the action of the stone longer than either normal dentin or enamel. We are consequently forced to the conclusion that the wasting of the dentin is not accelerated by the action of the acid; it may, with the exceptions given below, even be retarded or completely prevented by it. We can ordinarily have wasting of the dentin in the presence of an acid reaction only when the mechanical action is so strong that it wears away the dentin in spite of the decalcification. As a rule, any considerable

acid reaction at the neck of the tooth results in caries and not wasting; or we may have both occurring side by side; or caries may follow upon wasting through a change in the habit of brushing, or when the gums grow partially over the erosion cavity, thus preventing the further action of the brush and furnishing a lodging-place for the food.

Notice that in all of the experiments the mechanical action was made to correspond in intensity to the chemical, and that in all cases where the effects characteristic of wasting were produced it was necessary to bring a preponderance of mechanical action into play. Take, for example, the tooth No. 4 in Fig. 28 (experiment 20), where the brushing has just barely sufficed to keep pace with the decalcification. One minute half-hourly, or forty-eight minutes daily, represents a friction more than one hundred times that which the individual tooth ordinarily receives, whereas the strength of the acid employed is not more than twenty-five to fifty times what it would require to be in the mouth to have any action at all.

I have frequently asked myself the question whether the brushing and the amount of tooth-powder employed in producing the effects which I have described may not represent a greater amount of friction than is usually produced in cleaning the teeth. I do not feel at all sure, however, that such is the case, as I have taken particular pains that no more force should be exerted than in brushing the teeth in the mouth. We have a certain measure of the friction produced in the wearing of the brushes and in the amount of powder used.

In the case shown in Fig. 19, two boxes of tooth-paste were used and two brushes worn down, to produce a result which might represent the work of ten to forty years in the mouth, during which time on a very moderate estimate at least twenty to one hundred boxes of paste and five to twenty tooth-brushes would be used up.

With respect to the retarding influence of acids on wasting of the dentin, it depends very materially upon the nature of the acid. Those acids which rapidly

decalcify (soften) the dentin, of which we may take hydrochloric and lactic as types, most readily retard the wearing away by friction; while those which act slowly on the dentin (oxalic, tartaric, etc.), as well as those which have a macerating effect on decalcified dentin, may be wanting in this influence. (See under division IV.)

The very important question here arises as to whether the friction of the lips and cheeks in talking and eating is sufficient to represent the necessary me-

tells us this, since we know that where veritable decalcification of either the labial or buccal surface takes place, the decalcified tissue is never rubbed away by friction of soft tissues or of the food. It may be barely possible in the case of races that live on roots, edible earth, etc.

Therefore I am of the opinion that among civilized races, in order to produce wasting of the enamel through the agency of acids, there must be some mechanical factor in operation beyond that which is naturally present in the mouth;

FIG. 29.

Action of acid calcium phosphate in conjunction with friction during two and one-third years.

FIG. 30.

Friction in conjunction with water during two and one-third years.

chanical factor in the production of wasting. A study of the large amount of experimental material at my disposition has led me to the conclusion that under ordinary circumstances it is not. It certainly is not so in the case of the dentin, and although the decalcified enamel yields more readily to friction than the decalcified dentin, still I have found—especially where the process of decalcification is carried on very slowly, as it must be in the mouth—that a considerable amount of friction with the brush is necessary, otherwise we will find on drying the tooth with warm air that the surface has a chalky, opaque appearance.

Hence, I infer that even in the case of the enamel, the mechanical action must be more considerable than that which is produced by the friction of the mucous membrane. Our clinical experience also

and that in the case of the dentin, unless this factor is fairly strong, the action of the acid will result only in softening and decay. I fully recognize the potency of acids in accelerating the progress of wasting as far as the enamel is concerned; given the acid and the necessary mechanical factor acting together, the process will spread upon and through the enamel much more quickly than where only the mechanical factor is in operation. This is well illustrated by the following experiment:

In a mandible, the teeth of the left side were treated with a $\frac{1}{2}$ to 1 per cent. solution of acid calcium phosphate applied on cotton. The right side was treated in like manner with water, both sides being brushed twice a day with different powders for two and one-third years.

It will be seen by the photographs (Figs. 29 and 30) that the destruction of the enamel

is much more extensive on the left side (Fig. 29) than on the right (Fig 30). The brushing was begun one month later on the right side, but this in a period of twenty-eight months is a negligible quantity.

WHICH ARE THE ACIDS THAT MAY BE CONCERNED IN WASTING?

From the results of the experiments recorded above under divisions II and III, I think we can draw no other conclusion than that *any acid or acid salt which possesses the power of extracting the calcium salts from the enamel, or of breaking up the connection between the enamel prisms, may accelerate the process of wasting*, provided the necessary mechanical factor works together with it. Furthermore, any acid or acid vapor which is sufficiently powerful to disintegrate the organic basis substance

of the dentin may cause wasting, with a minimum of mechanical action.

It is, however, altogether a different question whether acids actually play an important rôle in the process of wasting as met with in the mouths of our patients, and certainly the mere fact that litmus paper shows the saliva to have an acid reaction at any particular time does not of itself justify the conclusion that the cause of the wasting has been discovered. American writers on this subject, as a rule, state that the reaction of the oral fluids is acid in cases of wasting. Others pronounce the reaction to be alkaline; for example, Dill and Preiswerk (*Schweizerische Vierteljahrsschrift für Zahnheilkunde*, April 1903, pp. 126, 127). A similar view is expressed by Hintz, although he does not give the grounds on which his view is based.

(To be continued.)

A STUDY OF THE VASCULAR LESIONS OF THE DENTAL PULP, THEIR COMPLICATIONS AND CLINICAL SIGNIFICANCE.

By A. HOPEWELL-SMITH, L.R.C.P., M.R.C.S., L.D.S.Eng.,

EXTERNAL EXAMINER IN DENTAL SURGERY AND PATHOLOGY AT THE UNIVERSITIES OF LIVERPOOL AND BIRMINGHAM; ASSISTANT DENTAL SURGEON TO THE ROYAL HOSPITAL OF LONDON, ETC.

THERE are probably no other organs of the human economy which have a greater number of interesting and unique features than the teeth. This is true in many ways—anatomically, physiologically, and pathologically. And it is doubtful whether, in these latter days of scientific expansion and investigation, as much is absolutely known about them as has been discovered, for example, about the cerebro-spinal system, with its gross and minute anatomy, its varied functions, and its disease conditions. Controversy still occupies itself with such questions as the real nature and structure of the enamel and its method of formation, and the exact terminations of the non-medullated nerve fibers in the pulp; while the arrangement and course of distribution of the bloodvessels and nerve

fasciculi of the peridental membrane are quite obscure. There are many subjects of inquiry which as yet are unexhausted.

Of all the different tissues that go to form the component parts of a tooth, the pulp is the most interesting. It is likewise the most important, for on its vascular and nervous mechanism depends the vitality and therefore the utility of each unit of the masticatory apparatus. The strikingly singular character of the anatomical distribution of the vascular supply arrests attention, and the impartial observer who might be suddenly called upon to study fully and critically the diseases of the pulp as an entirely new field for his own exploitation would probably note that fact at the commencement of his laboratory experiments and experience.

ANATOMICAL CONSIDERATIONS.

Two facts stand out pre-eminently as being of great significance—(1) the absence of a collateral circulation in the pulp itself, and (2) the non-valvular character of the veins, which at the same time are non-collapsible.

(1) With regard to the former, it may be recalled that during the development of the teeth the tissues formed from each layer of the primitive blastoderm are supplied by two separate groups of vessels, of which the internal set, distributed to the mesoblastic structures, vascularize the dentin papilla, the dental sac, and the surrounding bone. In adolescent and adult pulps the branches of the internal set enter the apical foramina of the teeth usually as a single trunk, which may measure as much as 83 microns in width, to become almost immediately bifurcated and divided into many subsidiary branches, ending near the basal layer of Weil in an anastomosis of capillary loops whose individual lumina are roughly, on the average, about 8 microns in diameter.

If the lumen of the main artery, entering the apical foramen, is by any means occluded, the integrity of the whole of the vascular system is imperiled, as there are no collateral branches to restore the balance in the blood-stream. This actual condition is almost if not quite unique in the general anatomy of the body, though three parallels may be cited, viz. the absence of a collateral circulation in the terminal vessels of the brain, in the arteria centralis retinae of the eye, and in a lesser degree also in the walls of the heart.

These remarks apply with no element of uncertainty to the vascular system of the single-rooted teeth. It cannot, however, be asserted with equal confidence that the pulps of molars have no collateral circulation. The exact method of distribution in these larger teeth has never been ascertained, owing to the difficulties encompassing the performance of an artificial injection of the vessels in adult age. But clinically it would seem to be impossible for a collateral anastomosis to exist; and from an embryolo-

logical point of view the statement of Lepkowski¹ may most probably be relied upon. This observer shows (*Anatomischer Hefte*, 1901) that "In the germ of the two-cusped tooth there are present two bundles of vessels separated from one another," etc.

(2) Again, on account of the patency and non-valvular character of the veins it may be assumed that exogenetic influences in normal circumstances cannot affect the flow of blood in the pulp. The veins are not subjected to muscular or other external pressure, and in this respect agree with other similarly constructed tubes, such as the superior and inferior vena cava, the pulmonary veins, and those in the interior of the cranium and vertebral column, and long and short bones.

Hence it is observed that these two facts are conspicuously apparent, the first being probably of the greater importance, as the general systemic veins that are 2 mm. and less in diameter are unprovided with valves. But the significance of the absence of a collateral circulation on the causation of diseases of the pulp cannot be overestimated by the perspicacious and discriminating student.

GENERAL EFFECTS.

After due consideration of these anatomical conditions it is not a matter for surprise that lesions or degenerations arising from variations in the blood current or in the blood pressure in the dental pulp should be fairly common. So much is this the case that one would probably be not far from the truth in asserting that while teeth are so very frequently the victims of dental caries, they may also equally and simultaneously be subjected to internal retrogressive changes induced by a lowered or altered physiological resistance on the part of the pulp, through the unusual characteristics of its blood supply. This does not apply entirely to the normal individual, but more especially to those persons who suffer from disturbances of the circulatory systems.

It is well known that many persons

undergo a certain temporary discomfort For some reason or other the vessels be-
brought about by hyperemia of the pulp. come vicariously over-filled and undergo

FIG. 1.

Longitudinal coronal section of premolar with pulp *in situ*, showing thrombosis of capillaries and other vascular lesions. Prepared by the author's process; stained with Ehrlich's acid hematoxylin. (Magnified 45 diameters.) A, Branch of main artery. V, Enlarged vein. C, Capillary filled with thrombus. T, Thrombus becoming organized. F, Early stage of fibrification of pulp tissue proper. O, Odontoblast layer increased in width and in the number of its cells.

hydrostatic congestion, which presently disappears when the cause is removed or when there is a good outlet provided for a free flow. If, however, the intradental pressure is so severe as to prevent the occurrence of an efficient and quick relief, then the tissues degenerate and perhaps die, as they are unable, on account of their dentinal environment, to accommodate themselves to their engorged state.

Dr. Ferdinand Tänzer of Trieste², in an instructive paper, has recently emphasized this point. He there records a case—among others—where, on account of the circulatory irregularities in the internal genital organs and adnexa of a patient, the pulp of a tooth died as the result of the abnormally-increased intradental blood pressure. The introduction of metal fillings and cement floorings into carious cavities is sometimes followed ultimately by local pain, and the work of obturation is credited by the uninformed with being the cause of the odontalgia, while it is merely often due to either reflex nervous irritation or a rise in the local blood pressure. The author just quoted proceeds to summarize his remarks by saying that this increased intradental blood pressure may arise as a consequence of diseases due to circulatory deflections from the normal, to conditions of high nervous tension as in hysteria, to influenza, pregnancy, or occasionally as the result of traumatism.

It is thus clear that temporary engorgement of the vessels in the pulp tends to produce odontalgia of varying degrees of severity; but if this congestion be continued it leads eventually to death of the parts and cessation of pain. This may be brought about (a) slowly, when the tissues pass through the various stages of fibroid degeneration, or (b) rapidly, when moist gangrene supervenes as a result of thrombosis, and arterio-sclerosis and sudden death *en masse* takes place.

It is believed that slight rise of blood pressure produces no symptoms of neuralgia, though it can be readily conceded that nerve pain from other areas may be reflected to a tooth which is sound but whose pulp is somewhat hyperemic. For

instance, the effect produced by pressure on the supra-orbital branch of the ophthalmic division of the fifth nerve occasioned by wearing a tightly fitting hat or forage cap may be to induce pain in a maxillary canine whose pulp is hyperemic—which pain disappears at once on removal of the cause of pressure.

At the time that Dr. Henry Head³ wrote his remarkable observations on "Disturbances of Sensation, with Especial Reference to the Pain of Visceral Disease," and drew attention to certain well-defined areas of superficial tenderness of the skin, the study of the vascular lesions of the pulp had not been undertaken. His investigations were solely concerned with carious teeth, and showed that "As long as the pulp-cavity is not exposed the pain remains local. The patient will complain of an aching tooth and will point to the one affected." Local stimulation produces local pain (odontalgia), and "is exactly analogous to that produced by injuries to the conjunctiva or outer layers of the cornea." When, however, the pulp is exposed the pain alters in character and distribution (neuralgia). "It starts in the affected tooth, and darts or shoots into the face, forehead, neck, or ear." (Page 407.) It is practically certain that, today, increased intradental blood pressure in sound teeth would be added to Dr. Head's previous classification.

Fortunately, gangrene as a permanent termination of thrombosis is a contingency of comparatively infrequent occurrence from a clinical point of view, and it is with certain atrophic changes, slowly produced, that the writer desires to deal in the present communication.

Some years ago the author published an account of that common lesion of the pulp which is today spoken of as fibroid degeneration or reticular atrophy. An article from his pen was printed in March 1892 in the *Journal of the British Dental Association*, in which was described the ultimate phase of this degeneration. The pathological steps leading up to it had not, at that time, been investigated, and its etiology was not thoroughly elucidated. The opinion

was, however, expressed that it represented "the natural and usual termina-

he has enlarged his views on the subject. for he believes that the senility of the

Material having been meanwhile forthcoming, and sections prepared, he is now able to give an outline of the probably vascular and other lesions which combine to bring about this state, parenthetically noting that the same or similar degenerations have been seen and described by Black⁵, Walkhoff⁶, Wedl⁷, Rothmann⁸, etc.

fibers of the parts occur. "Sheaving" of the odontoblasts, with or without fatty degeneration, permanent distension of the arteries and arterioles, and rapid development of overgrowth of the fibroid tissue supervene until a well-marked reticular atrophy appears, and in later stages complete fibrosis of the organ, with disappearance of all cells and nuclei.

FIG. 4.

Details of early fibrification of pulp tissue. (Magnified 250 diameters.)

D, Dentin. *O*, Odontoblasts. *C*, Condensation of pulp tissue. *P*, Early fibrosis.

Probably this fibrosis or sclerosis is due, as a complication, in the first place to thrombosis of the capillaries and veins, and permanent dilatation through loss of tone (due to impairment of the vasomotor mechanism) or disease of the walls of the arteries, with or without tiny hemorrhages. This seems often to be succeeded or accompanied by a condensation or fibrification of the pulp tissue which lies between the basal layer of Weil and the substance of the pulp proper. A hyperplasia of the connective tissue

and every vestige of nerve bundle and vascular system.

PATHO-HISTOLOGY.

Longitudinal coronal sections of the pulps show to the best advantage these changes. (Figs. 1, 2, and 3.) The capillaries and small veins which are distributed to the peripheral parts are engorged. Very few are empty and none are stenosed. Under low powers of the microscope they present themselves as

dark long strands running for the most part in the vertical axis of the tooth. The corpuscles and blood platelets which they contain are appreciably altered in shape and size—due, no doubt, partly to post-mortem changes, partly to the histologi-

from their walls as a consequence of rupture. Small arterial cauliflower-like hemorrhages are seen frequently, at times among the odontoblasts, at times in the basal layer of Weil, and again at times in the substance of the

FIG. 5.

cal reagents employed—as these have not been specially directed to the preservation and staining of the blood elements—and partly also to those hemic changes which favor coagulation, to be presently described. They may partially or completely fill the lumina of the vessels, and are sometimes arranged in rouleaux; but in addition have in places escaped

pulp itself. The hemorrhagic infarcts may vary in constitution from a punctiform collection of a dozen or more corpuscles to a large mass, as in the photomicrographs. (Figs. 8, 9, and 10.) The endothelium of the tunica intima of these arteries and capillaries is altered, and the nuclei of its cells are indistinguishable. The larger arteries and larger veins are

distinguishing coats, and so have the veins, both classes of vessels having thinner walls than usual—a condition which pathologists would probably designate as hypoplasia or hyaline degeneration. (Fig. 15.)

The morphological effects of these vascular lesions on the surrounding soft parts is very noticeable. In some in-

stances the odontoblasts, which are flattened laterally, and their nuclei are planiform. They are gathered together into bundles or sheaves. (Fig. 5.) The “sheaving” of the odontoblasts is of very common occurrence. It has been noticed by other writers, particularly by Walkhoff, who gives photomicrographs of

fibrous components are rendered more prominent and tough.

The cells of the pulp proper possess nuclei which are degenerate in shape and small in size; their branches are increased in number and extremely well marked. Here and there, in varying degrees of intensity, there seems to be a thickening of the intercellular cementing substances

Organization of the thrombi is observed to be proceeding in places, leaving only a thin fibrous cord or hyaline plug coherent to the walls or completely filling it up.

CAUSES.

Turning from the patho-histological aspect of this study, it is expedient and

useful to inquire what possible factors have contributed to bring about this condition. Why has the blood coagulated? Why have the vessels become thrombosed and the soft tissues degenerated? Prob-

selves. The vessels quickly become thrombosed, for instance, after the application of arsenous acid to an exposed surface of the pulp, because the vessels are under hydrostatic conditions and in-

FIG. 13.

Thrombosis and hyaline degeneration of arteries. (Magnified 500 diameters.)

ably the absence of a collateral circulation predisposes to it; but its exciting causes cannot be so readily determined. This absence of collateral circulation would predispose to the onset of thrombosis in cases, also, where any obstruction of outflow existed, *e.g.* in cases of inflammation around the soft parts, or inflammation in the soft tissues them-

closed in a resisting wall of dentin. Any increased volume of fluid (blood) must be compensated by a corresponding outpouring—as there cannot be an adequate displacement of the surrounding parts, owing to their circumscribed nature—to afford the room required. (It must not be forgotten, also, that no lymphatics have ever been identified as

such in the pulp.) The thrombosis in this instance, which might almost be regarded as chemical or traumatic, is an early stage of acute inflammation, and is

zozero¹¹ in 1882, and Eberth and Schimmelbusch¹² in 1888, are the first of all the blood elements to accumulate on the vessel walls during coagulation, and

FIG. 14.

Details of Fig. 8. (Magnified 250 diameters.) H, Hemorrhagic infarct. R, Rupture of bloodvessel. D, Dentin. O, Vacuolated odontoblasts. F, Early fibrosis of pulp.

almost immediately followed by gangrene or death of the pulp *en masse*.

A thrombus may be the cause or the result of arteritis or phlebitis. It may be due to chemical changes in the blood itself or lesions in the walls of the vessels, as in degenerations. Osler¹⁰ has observed that in thrombus formation the blood platelets, fully investigated by Biz-

that the filaments of fibrin spread principally from these plate masses. They undergo viscous metamorphosis and also conglutination as explained by Thoma¹³.

The thrombi formed in the sections which form the subject of this paper are obviously neither entirely the "red" nor the "white" varieties, but are clearly for the most part of a hyaline character,

consisting of cells, platelets, fibrin filaments, and a colorless, semi-transparent, homogeneous material. They are entirely non-infected, although hyaline thrombi are generally associated with infected conditions.

atrophy, through loss of atrophic influences. The chemical changes are those undergone by the blood through systemic derangements such as anemia, chlorosis, and those which take place toward the end of exhaustive diseases.

FIG. 15.

Reticular atrophy of pulp with thrombosed capillaries. (Magnified 300 diameters.) H, Small hemorrhage near thin-walled vessel.

Thus it would seem that, in the dental pulp, chemical changes in the blood, plus the unusual arrangement of the terminal vessels, assisted by the *vis a tergo* which naturally leads to a certain amount of retardation of the flow and therefore coagulation—as first pointed out by Virchow—are the originators of the

The suggestion of infectivity can be at once dismissed, as all the sections which have come under the writer's notice have been obtained from teeth, of the young and old alike, whose macroscopical aspects appeared to be sound.

It is of course well known that the blood of chlorotic patients may especially

tend to produce diseases of the vessel walls—due, no doubt, to the great diminution of red corpuscles and the relatively greater number of leucocytes, and their slow movement along the walls of

accompanied by the formation of adventitious dentin, or any amyloid or fatty degeneration of the pulp; and in no specimen yet examined by the author have there been evidences of chronic

the vessels, together with an increased number of platelets. Marantic, anemic, and debilitated conditions which often form the sequelæ of long-continued and enfeebling fevers and diseases, probably also have the same or similar effects on the tissues of the vascular system.

The cases here presented are entirely free from intrinsic calcification, are un-

arteritis, atheroma or endarteritis, aneurysmal varix, phlebitis, or varicosity of the veins.

CLINICAL SIGNIFICANCE.

Of what value to the dental surgeon is a knowledge of the pathological states imperfectly sketched in the preceding

pages? Can it assist him in the more perfect performance of his daily duties? Certainly; for it is at once obvious that if an attempt be made to "cap" an exposure of a pulp which happened to be

manifest and indisputable. It is of course acknowledged that thrombosis and fibrosis are undiagnosable during life, but they may always be suspected in weak or unhealthy patients.

FIG. 17.

Details of thrombosis. (Magnified 250 diameters.) C, Thrombosed capillary. A, Artery. N, Nerve bundle.

diseased in this way, no matter how carefully or how aseptically the operation be done, no new secondary or adventitious dentin would be produced to heal the breach of surface; and also the obstacles surrounding the complete devitalization of the pulp by means of arsenous acid, or its painless extirpation by means of pressure anesthesia, become immediately

The knowledge might perhaps explain the deaths of pulps where no evident lesion could be ascertained.

And, finally, it is not difficult to believe that, when the blood system of the pulp is deranged in the way already described, it is deprived of its trophic functions with regard to the tissues around. Teeth lose their accustomed vitality and become

more susceptible to outside influences and disturbances. At first remaining in jectively, the degenerated pulp may begin to pass on its lowered vitality to the den-

situ, though affected by fibrosis, which exists unknown both subjectively and ob- tin and the peridental membrane. The former most probably is deprived of its

protoplasmic nourishment, wholly or in part, and undergoes more or less chemical or molecular change, and at times morphological change too, as seen in the photomicrograph Fig. 18, *D' D'*, becoming unduly brittle. The latter may easily and doubtless does share in the fibroid degeneration, which would assuredly sooner or later tend to loosening of the teeth in their alveolar sockets. It may, in addition, be hinted that perhaps this condition of lowered vitality may predispose the teeth to the onset of dental caries.

Enough has, however, been said to draw attention to the condition, and it is hoped that other workers in dental pathology may be hereby induced to correct, amplify, and complete the study of this fascinating subject.

GROUND PORCELAIN CORNERS WITH MECHANICAL ANCHORAGE.

By P. B. McCULLOUGH, D.D.S., Philadelphia, Pa.

(Clinic at the forty-eighth annual meeting of the Pennsylvania State Dental Society, Philadelphia, June 26, 1906.)

THE prepared shape of the cavity is that indicated by the lines of decay or fracture. It may form two plane surfaces with one angle (Fig. 1), or one of two other forms, each with a plane surface. For a corner with one angle, the vertical plane forms an obtuse angle with the base, thus making two flat surfaces to be fitted. The vertical plane, A, may be formed rapidly with abrasive paper disks, and the surface made flat by means of the side of a vulcarbo disk and a Murphy file. The cervical plane, B, is finished with the edge of an abrasive disk and a narrow file. Any make of detached pin crown best suited in mold

and shade is selected and ground to fit the space.

The section to be used is outlined with a corundum disk and broken off. The vertical plane surface is first ground to size, then the cervical end is ground to proper length, when both surfaces are trued on the side of a fine stone on the lathe. (Fig. 2.) Throughout, care must be observed not to chip the edge.

A cavity is cut in the tooth so as to be shallow at the cervical angle with a flat base and pointing to the incisal edge (Fig. 1), where it becomes deepest, forming the only undercut, so that the matrix is drawn by turning out from the cervi-

cal end or angle. In this cavity is adapted 2/1000 platinum. Should the puncture be a considerable one, a second smaller matrix may be shaped over the puncture and adapted with wet spunk, which is left in place until invested. The matrix is filled flush with any filling

FIG. 1.

FIG. 2.

gold packed lightly, and 22-k. solder flowed through. This inlay, returned to the cavity, is ground flush with the edge of the latter, taking care not to injure the enamel.

The porcelain section is grooved vertically with a diamond disk, as a starter

FIG. 3.

FIG. 4.

only; then a piece of clasp-gold wire, F, of about No. 18 gage, is held in a screw chuck sold for the engine (Fig. 3), and with this wire used like a drill, the groove is cut into from the cervical plane surface, using carborundum powder in glycerin as the abrasive. This hole (Fig. 2, E), is so formed that while it is open on

the vertical plane surface where the wire is exposed it can only be withdrawn from the end by which it enters. This wire is cut off flush with the base of the inlay, and if necessary its exposed side is ground flush with the flat porcelain surface.

With the wire point in the porcelain, and the gold inlay in the tooth, the porcelain is rubbed to and fro on the tooth with wet pumice to finish the joint. Having the mouth napkined, the sections washed and dried, the inlay for the tooth in place, then the wire point, in the porcelain and warmed, is touched with the faintest particle of hard wax, a blast of hot air directed on the gold inlay, and the porcelain pressed to place. With the withdrawal of pressure the porcelain drops off, leaving adherent the gold sections, which are then removed, invested, and a particle of low-karat solder placed at a convenient spot to unite the sections. (Fig. 4.) With one mix of cement the gold is first placed, then the corner slid to place and held.

If, when the decay is such that after the vertical plane at the labial surface has been finished there still remains the unprepared edge of the cavity more extensive on the palatal surface, then this part is prepared independent of the labial plane, the matrix adapted over the edge and filled with the melted gold, so that when returned to the cavity the exposed surface is cut flat and flush with the labial enamel edge. By this means the joint with the porcelain on the palatal surface is made with the gold, thus obtaining a plane surface without cutting away labial enamel which it may be desirable to retain.

When the case presented admits of being ground to a plane surface the operation is made much easier. With the finished plane surface extending from a point at the incisal edge to the gum margin (Fig. 5), a cavity is cut of uniform depth and with a flat seat, G, and, as above recommended, a gold inlay is made. After the porcelain has been ground to fit, a small round clasp-gold disk is made of about No. 22 gage, which is held on a screw-disk mandrel (Fig. 6), and the

gold used with carborundum powder to cut a semicircular groove in the porcelain. (Fig. 7, H.) When this groove is cut as deep as the mandrel will allow the disk to

FIG. 5.

FIG. 6.

go, the disk is cut in halves, one piece filed flush with the ground surface of the porcelain, and, as in the first case, waxed to the inlay in the tooth, removed, invested, and soldered. (Fig. 8.)

It will be seen that in this class of cases a very delicate tapered point of porcelain remains at the joint with the tooth at the incisal edge, supported only

FIG. 7.

FIG. 8.

by cement—which is no support; therefore, since it cannot be expected that this point will last without protection, the following is offered as being used always with this as well as with the class first described, but was not given before in order to avoid repetition:

After the gold section has been placed with cement and the porcelain is in position ready to press to place, a piece of No. 60 gold foil or a gold roll is inserted in the joint to about one-sixteenth of an inch, then the porcelain is pressed home

and held until the cement has set. There being free escape for the cement throughout the joint, and it being least confined at the incisal edge, it will be seen that under pressure the cement is practically eliminated at this point, leaving the gold as a permanent support. (Fig. 9, I.)

That this gold cannot be seen may be believed when the thickness of No. 60 foil, as seen looking at its edge, is considered.

When the restoration is one where the entire incisal edge is gone, no change in the technique is indicated. The cavity in the tooth is prepared for the inlay (Fig. 10, J), and the porcelain cut with

FIG. 9.

FIG. 10.

the gold disk, one half of which, K, is soldered to the inlay, J. Of course, in this class of cases the gold protection for the porcelain is not required.

The head of the mandrel, as well as the head of the screw carrying the circular gold disk to grind the cavity in the porcelain, is cut down, so that without the heads the disk may penetrate deeper in the porcelain.

Each of these cases presupposes vital teeth; in the first two, if devitalized, instead of avoiding the pulp by cutting toward the incisal edge, anchorage would be obtained by inserting a cone-shaped tube in the canal, filling it with melted gold and proceeding as above recommended.

The increased strength obtained by

this method, using the first case described as a basis of measurement for comparison with the methods usually practiced, is shown by consideration of the following features: The inlay fitting the cavity in the tooth is so shaped that it can be dislodged only by turning it out and down from the cervical end. When the

wire fitting the porcelain is soldered to the inlay, the former can be detached only by drawing down; thus every possible direction of the application of force is resisted mechanically by the gold bridging the joint, the cement serving to keep the corner from falling in the direction in which no force is applied.

A NEW AND EASY METHOD OF MAKING PERFECT GOLD FILLINGS.

By **W. THOMPSON MADIN, L.D.S. Eng. & Glas.,**

LECTURER ON OPERATIVE DENTAL SURGERY AT THE BIRMINGHAM UNIVERSITY; HONORARY ASSISTANT
DENTAL SURGEON TO THE BIRMINGHAM DENTAL HOSPITAL.

THE following is a method demonstrated at the last annual meeting of the British Dental Association in London, and set forth by me in a paper in the *British Dental Journal* of November 15, 1905. As the advantages of it have been further confirmed by experience, and as the growing tendency of the best operators is toward combination fillings, I am emboldened to describe it more fully. Dr. Head and others have often given evidence of the advantages of cement with metal fillings, and recently Dr. J. F. P. Hodson has described a method of procedure of his which is very much the same as mine.*

For many years I have distrusted fillings the material of which did not stick to the walls of the cavity, and for a long time have rarely made an amalgam filling which was not pressed into wet cement. In the case of gold fillings, I think that observant men will generally agree with me when I say that only here and there is found a genius who can consistently fill cavities with gold so that the gold is perfectly adapted to the walls of the cavity, and the filling water-tight.

I am constantly seeing fillings made by myself and others which by the tell-tale blue discoloration or the white opaque ring around them show that caries is still progressing, and that the filling is useless.

We know that this condition practically never occurs with inlays; but inlays, beautiful as they are, and undoubtedly useful as all who have had experience of them must agree that they are, have two weak points—they are only held in by the adherence of the cement, and they do not protect weak walls, because the material is not of itself strong enough to bring over beveled edges. Gold, still the king of all fillings, can by this method be keyed into the cavity by undercuts, whilst there is a lining of cement which perfectly obviates the old risk of non-adaptation, and tends to do away with the showing through of the gold in the case of thin enamel on labial surfaces; and the gold, being tough, may be brought over weak edges, protecting them as does no other material that I know. It very largely reduces the time necessary, too, as it does away entirely with starting-points and retaining-pits; although, of course, in using cohesive gold all through, as is done in this case, one can never hurry unduly. I use this method now

*See report of the New York Odontological Society meeting of April 17, 1906. *DENTAL COSMOS*, 1906, vol. xlviii, p. 1121.

in every case; it is applicable to tiny cavities as to the largest contour fillings, and makes gold filling as easy and sure as using amalgam. In filling cervico-labial cavities—previously a difficult class of cavity to deal with on account of the trouble in obtaining dryness—all difficulty disappears, as the rubber dam and the cervical clamp are quite unnecessary; though in all other cavities the rubber being so easily applied is a great advantage. The cavity is thoroughly opened up, and in this I may say we have learned a great deal from the inlay workers—their necessity for open flaring edges showing the ease with which patches of softened carious dentin might be left in hidden corners. It is then given a retentive form by undercuts or dovetails, and the simpler and shallower and less angular these are the better. The cavity edges it is my habit to leave quite square by means of a disk, so that the filling may be brought over and the full thickness to the outside inclosed in gold for protection; the exact opposite to the sharpened-from-inside edge of an inlay cavity.

The rubber having been applied, either before preparation or after, as best suits the operator's taste, and the cavity dried, a piece of No. 30 gold foil is cut exactly as for taking an impression for an inlay; thin cement is now mixed (again as for fixing an inlay), and with it the inside of the cavity is smeared well over, and the No. 30 gold foil is pressed home into it with amadou, in the usual impression method. Special pressure is given in the direction of the undercuts, and often a ball burnisher is pressed in that direction also. This gives an undercut cavity, beautifully lined with gold, with cement in every possible irregularity. It is important to see that the edges of the cavity show up quite sharply, as only by that can one tell that when the filling is finished there will be no cement at the

margins. This is easily done, however, with pressure on amadou, followed by a burnisher around the edges; thus, though I examined all my early fillings with a magnifying glass, I never found a trace of cement around a finished filling. It will now often be found that the foil has been split, and a little cement is oozing through; this is not at all a disadvantage, as a piece of gold patted gently over the split stays in position at once. Into the gold-lined cavity, without waiting for the cement to set, I loosely place several pieces of sponge gold, beginning with the undercuts, and press them home, again with amadou; then condense thoroughly with hand pluggers, and finish the filling in the usual way. Any cohesive gold which the operator is in the habit of employing may be used; I personally use sponge gold, topping up with two or three layers of No. 30 as used for the impression, but that is a matter for purely individual taste. In the special case of the cervico-labial cavity mentioned above, the cavity is prepared, dried, and kept dry with napkin or wool roll, and the impression gold overlapping the gum effectually prevents any oozing. I have recently had an extensive case of so-called erosion on the surfaces of the upper and lower teeth, and the latter, which previously I should have regarded as very difficult, were, with the help of a saliva ejector, filled as easily as they could have been had amalgam been the filling material.

This mode of working has entirely altered my methods of practice. Previously, subscribing to the old adage that "In proportion as a tooth needs filling, gold is the worst material for the purpose," I did not dare use gold in very weak teeth; now I know that the protection obtainable at the edges, and the adherence of the cement, make gold the ideal filling for teeth with frail walls.

THREE ORTHODONTIA CASES.

By S. MERRILL WEEKS, D.D.S., Philadelphia, Pa.

(Clinic at the thirty-eighth annual meeting of the Pennsylvania State Dental Society, Philadelphia, June 28, 1906.)

CASE I. Fig. 1 represents the casts of the mouth of a young lady seventeen years of age. The conditions are of such an unusual nature as to lead me to believe that a description of the case would be of interest to the profession. It came under my observation in October 1905.

to end in the molar region. This condition seemed to become progressively although slowly worse, eventually affecting the facial balance.

On preparing casts of the two arches and carefully noting the condition, I found that a degree of contraction of the upper arch—amounting to about half the

FIG. 1.

Briefly, the history is as follows: Until within two years the teeth were in a beautifully normal occlusion; at least such was the firm conviction of not only the patient and her family, but likewise of her dentist. About that time it was noticed that the teeth of the upper left side failed to meet the lower teeth, and the difficulty seemed to be wholly with the upper arch, it being most pronounced at the median line, diminishing gradually,

width of the teeth bucco-palatally—had taken place from the canine backward, and only on the left side. This feature of the case I believe will become significant when considering the etiology of the deformity. The left side was also in mesial occlusion, viz, the lower teeth were occluding distally to normal in their relation to the upper teeth. This would place the case in Class II, division 1 or 2—depending on whether it was caused

by abnormal breathing—and in the subdivision, because it existed only on one

able wrinkle, extending from the ala of the nose to a point beyond the angle of

FIG. 2.

FIG. 4.

FIG. 3.

FIG. 5.

FIG. 6.

side. I found also that the muscles of the lips and cheek were being drawn backward and upward, causing a notice-

the mouth, as shown in Figs. 2 and 3, which are reproductions of trimmed photographs. A careful study of pho-

tographs taken several years previously seemed to show no such condition, and it was the opinion of the parents that it was fast assuming more marked proportions.

of mouth-breathing, and the features did not seem to indicate the possibility of such a cause.

The failure of the teeth of the upper left side to occlude properly appeared to

FIG. 7.

FIG. 8.

Some of the factors leading to this condition are obscure, and I shall pass them by without attempting to explain particularly the cause of the contraction of the upper arch, as I could obtain no history

indicate by the existing relations that the cause was wholly in the upper arch, and the fact of the condition being more marked at the median line and diminishing gradually would likewise seem to

point to the maxilla as the initial etiological factor. The author is of the opinion that some change had taken place in the sutures, and, to substantiate this, a radiograph shows distinctly an incomplete union between the halves of the maxilla at the median suture. The cause would seem to be indicated by the conditions existing in the mouth. It is to be noticed that the intercusping of the

bodily, and its progressing evenly would seem to indicate that a movement of the alveolar process, if not of the maxillary bone, has occurred. The degree of success of the treatment is indicated by the second photographs (Figs. 4 and 5), and by the photo-engraving of the cast taken at the completion of the work. (Fig. 6.)

Case II. This was the case of a boy

FIG. 9.

teeth on the right side is normal, while on the left side the teeth had been, and were now in the posterior part of the mouth, occluding with the cusps end-to-end. Such a condition would bring a greater degree of pressure on the left side during mastication, and would be sufficient, the writer believes, to account for all the subsequent changes.

The treatment consisted in expanding the arch so that it would properly occlude outside of the lower arch. It was necessary to accomplish this not only to allow for the proper relation of the upper and lower teeth, but also to retain the proper relation of the planes of occlusion between the lateral halves of the arch. The elongation of the teeth of the upper left lateral half of the arch was carried out

fourteen years of age. It is a case of Class I, in which the irregularity was caused by the entire absence of the upper right lateral incisor and by the abnormal shape and size of the upper left lateral incisor. The posterior teeth were practically in normal position. (Fig. 7.) The requirements of the case were (a) to move the upper left lateral to labial occlusion and to provide it with a crown presenting a natural appearance, and (b) to move the right central incisor to the left, in order to provide sufficient space for an artificial upper right lateral.

The difficulties that were encountered were found in moving the right central without tipping it, and in securing sufficient anchorage without interfering with the existing normal relation of the mo-

lars and bicuspid. The latter was obtained by a careful adjustment of the appliances, so as to utilize the posterior teeth of both sides of the upper arch. To Dr. W. W. McKay should be given

sary to improve the facial lines by securing a normal prominence of the mandible. (Fig. 9.) It was brought about by a lateral expansion of both arches, and by moving forward the lower arch to

FIG. 10.

the credit for so satisfactorily supplying the missing structures. The left lateral incisor was supplied with a jacket crown, and the right lateral incisor was substituted with a removable piece attached to the canine, and provided with a spur resting upon the right central incisor. (Fig. 8.)

Case III. In this case it was neces-

its normal relation with the upper. The case responded to the treatment so easily as to indicate that the temporo-maxillary articulation had been in an abnormal relation at the beginning of the treatment. The patient was fifteen years of age, and the result as affecting the regularity of features was highly satisfactory. (Fig. 10.)

A UNIQUE METHOD OF SUPPLYING A MISSING ANTERIOR TOOTH.

By EDWIN E. DAVIS, D.D.S., Boston, Mass.

(Clinic at the forty-second annual meeting of the Massachusetts Dental Society, held at Boston, June 6, 1906.)

THIS is a very simple, useful, and so far as my experience goes, exceedingly satisfactory method of substituting a natural tooth by a porcelain facing, and in such a manner as to leave no visible trace of the operation.

The second bicuspid or first molar on the same side on which the loss has occurred is prepared for a gold crown. The

of determining the best tooth to be crowned. A gold crown of fairly heavy thickness is perfectly fitted and adjusted to a perfect occlusion with the opposing teeth.

Just a word here in regard to the reinforcement of the grinding surface of the crown. Cut a piece of gold or platinum of No. 22 gage that will just drop

selection of the tooth to be crowned is determined by the peculiar characteristics of each individual mouth. If, for instance, the teeth are not much exposed to view when the patient talks or laughs, the second bicuspid may be used, but if the teeth are exposed considerably it is better to crown the first molar. Sometimes, and in fact frequently, one or the other of these teeth is quite largely filled or is broken down; or conditions of occlusion may be such as to govern the matter

into the crown and cover the grinding surface. Swage or burnish it to fit the contour of the occluding surface, and solder it to the gold surface. This will afford an even and safe protection against wear.

With the crown in position on the tooth, an impression is taken with modeling compound, the crown removed and replaced in the impression, and a plaster cast run. We shall now have a model of the mouth with the gold crown in posi-

tion. A facing of proper shade, shape, and size is selected and backed with gold, allowing the backing to reach only to the cutting edge and not to cover it. It is then ground to fit the cast and waxed into position from the inside. Thin plaster is run over the outside of the facing and cast, to hold the facing firmly in place. The wax is removed, and a shallow furrow carved on the roof of the cast from the anterior side of the gold crown to the facing, following the gum margin at about one-eighth of an inch from the teeth. This is to allow the connecting bar to set firmly and snugly against the roof of the mouth.

Now a piece of platinum wire of No. 13 gage is flattened slightly on the anvil, or it may be rolled, and the flat side is rounded with a fine file. This is bent and twisted so as to conform exactly to the

carved groove in the cast, and to merely touch both the crown and the facing. Held in position with a bent pin inserted into the cast, it is soldered at each end, and the case is removed, finished, and set in the mouth, care being taken to hold it in position until the cement is quite hard, as it is desirable that the bar should set firmly against the gum.

The pressure of the bar is unnoticed after a short time, and little or no interference in talking is experienced.

The accompanying illustration is a reproduction of a cast from the mouth of a young lady who had lost a retained deciduous upper canine, with no indication of the permanent canine erupting. Some three years have elapsed since the operation was carried out, and the case is in perfect condition today.

REMOVABLE BRIDGES WITH GOLD INLAY ABUTMENTS AND SADDLE AND VULCANITE ATTACHMENT.

By J. A. PENNINGTON, D.D.S., Pittsburg, Pa.

(Clinic at the meeting of the Pennsylvania State Dental Society, held at Philadelphia, June 28, 1906.)

IN the construction of this work we begin with the swaging of the saddle or plate. In swaging be careful not to allow the saddle to extend under any undercuts or to impinge on muscles, as, it being held perfectly rigid, the resistance is too great to allow free action of the muscles—a condition which would result in a certain degree of irritation. As all pins and tubes must be parallel and draw direct, a saddle extending beneath undercuts will drag, likewise causing irritation.

PREPARATION OF CAVITIES.

As shown in Fig. 1, A, A, prepare as broad and deep cavities as the teeth will

admit of without weakening them, with square seats and walls at as near a right angle to the seat as possible, slightly diverging toward the occlusal surface so that the matrix will draw, and slightly beveled on the occlusal edge so that the inlay will protect the enamel walls.

TAKING IMPRESSION OF THE CAVITY AND MAKING THE INLAY WITH TUBE ATTACHMENT.

Use matrix platinum foil 1/1000 of an inch in thickness and prepare the matrix as for a porcelain inlay. After the matrix is well burnished and placed in the cavity, insert the tube through the matrix into the enlarged canal, being always

FIG. 1.

Prepared cavities in first bicuspid.

FIG. 2.

Cavities prepared in the inlays, with tubes.

FIG. 3.

Inlays with split pins. The inlays, D, D, restore the natural contour of the abutment teeth.

careful to have all the tubes parallel. Wax the matrix and tube in place with hard wax, remove, invest, and solder

move the impression with all the parts in place. From the latter prepare a cast. In these inlays with tubes, prepare

FIG. 4.

Completed piece on cast.

them together, using 20-k. or 22-k. solder, at the same time restoring the contour of the tooth.

After the inlays with tubes are made

cavities as shown in Fig. 2, c. For these cavities second inlays are prepared, to which the split pin is attached. In preparing these cavities have as broad and

FIG. 5.

Bridge removed from cast showing cap on molar and gold inlay and tube on lingual surface of canine to receive split pin and inlay attachment.

FIG. 6.

Completed bridge shown in Fig. 5, on cast.

and the saddle is swaged, place these parts in position in the mouth and secure an impression of them. Allow the plaster to be a little stiff so as to force the saddle well into the soft tissue. Re-

as deep a seat as the inlay will admit of, with buccal and lingual walls at as nearly a right angle to the seat as possible, and with sufficient slope to admit of drawing the split pins. To this cavity adapt a

matrix of pure gold, gage No. 38 to 40, and through the latter insert a pin into the tube. Wax the several parts, remove them, and proceed in the same way as

FIG. 7.

Cast showing capped molars and cap and tube, on root of left central incisor.

FIG. 8.

Bridge with telescoping crowns and cap and split pin to fit root of left central incisor.

with the first inlay, being careful in soldering to restore the contour of the tooth as shown in Fig. 3, D, D. This completes the inlay abutments.

When the abutments are made, place them in position with the saddle on the cast; wax the inlays with pins attached to the saddle—using hard wax in all this work; remove them from the cast, invest

and solder them, at the same time soldering cleats to the saddle for the support of the rubber attachment. With the piece so far completed, take the bite, articulate it, and proceed as in the case of ordinary dentures. Fig. 4 shows the work completed on the cast.

The cases shown in Figs. 5 and 7 are constructed in the same way as that shown in Fig. 1, with the exception of the pin and tube and the telescope abutment

FIG. 9.

attachments, which are constructed according to the method devised by Dr. Fred A. Peeso.

Fig. 5 shows a bridge removed from the cast, also showing the cap on the molar for the telescope, A, and the gold inlay and tube in the lingual surface of the canine for the split pin and inlay attachment. Fig. 6 shows the completed work articulated.

Fig. 8 shows a bridge removed from the cast (Fig. 7) in which the molars have been capped to receive the telescoping crowns of the bridge. A cap and tube have been inserted in the root of the central incisor for the reception of the split pin and cap attachment. Fig. 9 shows the completed work articulated.

CORRESPONDENCE.

FORMALIN AND TRICRESOL IN COMBINATION IN THE TREATMENT OF PUTRESCENT PULPS.

TO THE EDITOR OF THE DENTAL COSMOS:

Dear Sir,—A most interesting and important essay on dental therapeutics, under the title of "The Rational Treatment of Putrescent Pulps and Their Sequelæ," appeared in the issue of the *Cosmos* for May 1906, by Dr. J. P. Buckley of Chicago.

This important subject should have more attention than has been given it of late years, and it may not be out of place if you will permit me to give a few statistics concerning the use of this valuable combination of drugs, viz, formalin and tricresol.

Some two years ago I began the use of this combination for putrescent canals, and its use was attended with such surprising results that I began a series of experiments with it. I do not remember where I first heard of the use of these medicines in combination, but as Dr. Buckley claims priority we will give him the credit, and it may be that it was his former article on the subject that I read.

While in practice in San Diego, Cal., I used this formula, and, like Dr. Buckley, found that if confined to the treatment of those cases where it is indicated it will give the results sought in *almost* every case—not in every case, as we have some failures with the best of remedies. However, I have attributed the failure to my faulty manipulation in cleansing and properly filling the canal after the remedy had been used. On the other hand, if this remedy be used in cases where the pulp is not putrescent or gangrenous, it will raise trouble that will

in all probability cause the dental surgeon to condemn it as unfit and dangerous.

Since entering the United States service and being appointed to duty in the Islands, I have had abundance of opportunity to test the merits of Dr. Buckley's formulæ—as in this country the soldier soon became emaciated, and is found seeking dental services. In a great many cases where the pulps would not have putrefied in the States they have done so over here, and the number of men to be treated makes it evident that we must find some remedy that can be inserted in a very short space of time and still be potent enough to do what is required of it. Formalin and tricresol have done the work, and I am of the opinion that fewer failures will result from the use of this combination of medicines than with any other known to the profession today. My experience with it has been a most happy one.

The solution of mercury bichlorid has never been used by me after the dressing with the former drugs and the good results obtained notwithstanding would tend to demonstrate the fact that it is not a necessity. I have been using a mild sedative as an after-treatment, and filling the canals as soon as odor was absent; the sooner the better, provided the inflammatory conditions have subsided.

Yours truly,

CROXTON L. RION,

Dental Surg. U. S. Army.

CAMP JOSSMAN, GUIMARAS, P. I.

July 7, 1906.

PROCEEDINGS OF SOCIETIES.

MASSACHUSETTS DENTAL SOCIETY.

Forty-second Annual Meeting.

(Continued from page 81.)

CLINICS.

Dr. C. H. GERRISH, Exeter, N. H.
 "Napkins and Cohesive Gold Foil."

This clinic consisted of the making of gold fillings of non-cohesive in combination with cohesive foil; also practical demonstrations of the use of napkins for keeping the mouth dry in minor operations lasting as long as a half-hour.

Dr. L. C. TAYLOR, Hartford, Conn.
 "Methods of Filling Small Cavities in Children's Front Teeth."

The object of the clinic was to show the importance of filling very small cavities in the teeth of children as young as eight or ten years of age. Dr. Taylor used for this purpose cement and gold in combination; just sufficient amount of gold in finishing the filling to protect the cement and prevent it from dissolving out of the cavity. This operation is performed with the aid of heated instruments.

Dr. C. WESLEY HALE, Springfield.
 "Adapter for Abscess Syringe."

Dr. Hale gave a demonstration of a little appliance which he termed an "adapter," to be used in connection with the syringe, whereby the operator is enabled to carry medicine into cavities and root-canals and through the fistulæ of abscesses.

Dr. A. W. DOUBLEDAY, Boston. "Combination Inclined Plane and Retaining Appliance."

This appliance (Fig. 1) is constructed to take the place of those which have heretofore been composed of all metal, and have the plane soldered to the anterior portion of an appliance which is cemented to two or more teeth; for the reason that with such an appliance a great many of the shredded or fibrous

FIG. 1.

foods give no end of disturbance. In most cases where this appliance has been used, the arch has been expanded and the anterior aspect of the mouth greatly modified, often to the extent of rotating one or more teeth. A vulcanite plate forms the substantial part of the appliance and covers the roof of the mouth, including the first molar. A platinized gold plane (with suitable attachments soldered to the back) is vulcanized in the correct position so as to properly draw the mandible forward at each closing of the mouth; also a platinized gold or Ger-

man silver wire of from No. 16 to No. 21 gage (according to pressure desired) is vulcanized into the plate, extending out through the approximal spaces between the canine and the first bicuspid, and across the labial surface of the six anterior teeth.

be removed. The anterior wire serves to retain the arrangement of the anterior teeth, and pressure may be increased or relieved on any of these teeth by a slight shaping of the wire with contouring or other suitable pliers.

Figs. 2, 3, and 4 show an example of

FIG. 2.

FIG. 3.

FIG. 4.

The plate serves as a retainer for the expanded arch. The inclined plane at the same time modifies the bite, which in most cases, especially in persons under twenty years of age, will have become fixed in from six to eight weeks, so that this portion of the appliance may

results obtainable with this appliance. It may be removed by the patient at will for cleansing the teeth. Hearty co-operation and appreciation on the part of the patient make it unnecessary to cement this appliance to the teeth in order to have it continuously worn.

Dr. H. CARLTON SMITH, Boston. "Appliances Used in Testing Amalgams, Cements, Etc."

The clinic given by Dr. Smith illustrated the course in dental chemistry given at the Harvard Dental School. This course aims to make practical application of chemical science to the problems of dentistry, and the clinic included the simpler methods of salivary and urinary analysis, which might serve to indicate more or less obscure systemic conditions bearing on dental diseases. The object of the clinic was not to show the very little that has been done up to the present time, but rather to stimulate interest in such investigations, in order that much more may be accomplished.

Methods of teaching were also shown, together with samples of laboratory work, this work including the preparation, tests, and analysis of amalgam alloys and cements, also the micro-chemical examination of local anesthetics, etc.

Dr. N. P. BUGBEE, Springfield. "A Method of Bridge Attachment."

This clinic consisted of the demonstration of a bridge extending from the first molar to the first bicuspid. A gold cap was placed over the molar, and, as the bicuspid had a large gold filling on the distal surface, a groove was made in the filling and a bar to rest in this slot, thus allowing for the movement of the teeth as in a normal articulation. Where teeth are banded by crowns on both abutments this movement is lost and the value of the teeth impaired.

Dr. E. W. MOORE, Newport, N. H. "A Card System for Dental Accounts."

Dr. N. A. STANLEY, New Bedford. "Porcelain Molar Crown."

The present crown, while essentially the same, has been somewhat simplified, and is more easily constructed than the one described a year ago at this clinic. In place of three pins, he uses a staple (Fig. 1) of No. 18-gage pure platinum wire. These two pieces of platinum serve three purposes. The thin piece of plate

makes a perfect joint; and the loop holds the porcelain and prevents the ends from spreading through contraction in baking. The staple can readily be fitted to the holes in the tooth. Corresponding holes are made in the plate, and the staple is

FIG. 1.

FIG. 2.

soldered to the plate with pure gold. After the cap has been malleted, burnished and trimmed to fit the end of the root accurately, cover the loop with sufficient wax preparatory to securing the bite; the wax is cooled by means of cold or iced water before removing it from the mouth. A sufficiently accurate cast can then be obtained to finish the operation. Before setting the finished crown (Fig. 2), "butter" the platinum with Evans' gutta-percha cement in order to obtain as perfect a joint as possible. The application of a little eucalyptus oil and the use of a sharp-pointed instrument will enable one to trim away the surplus gutta-percha.

Dr. A. J. SAWYER, Manchester, N. H. "To Band a Root so that the Gold will Restore Accurately the Contour between the Root and the Crown."

Prepare the root by beveling considerably toward the crown end. Cut the band sufficiently small to allow of its being fitted to the smallest portion of the prepared end of the root, so that when pressed to place it will stretch and closely fit the beveled portion. Now grind the root, with the band in position, as short as desired. Then grind any all-porcelain crown, preferably a detached-post crown, in length and occlusion to fit the case. Burnish or swage a piece of No. 35 pure gold to fit accurately the end of the porcelain crown next to the band.

Place the crown with the gold on the now banded root, and with the tooth

in proper position mark the outline of the gold band on the gold burnished over the end of the crown, so that both the band and the gold on the crown can be removed intact, and caught together with a very minute piece of solder on the lingual side only (just enough to hold the two pieces together). This is then replaced on the root and the crown put in position. As the band and crown plate have only been slightly caught together on the lingual side, there is left some latitude in the adjustment of the band and crown plate, which are now made perfect as to their relation to each other, although they need not necessarily fit closely together. Both the band and crown plate are now slipped off; the inside of the band and the side of the crown plate where the crown is to sit are filled with powdered asbestos mixed with water, and a little wire is twisted to hold the parts in position. Then on the outside of the band, and between the band and the crown plate, flow No. 22-k. gold solder, and then cement the crown, band, and post together in position on the root. When the cement is hard, the crown, band, and post are removed and the band is finished down even with the crown. It is then ready to be cemented upon the root permanently.

Dr. A. J. SAWYER, Manchester, N. H.
 "To Replace a Broken Facing on a Bridge in the Mouth."

Cut or grind off the old pins even with the backing. Then with a drill the size of the platinum pins, drill through the backing at the point of one of the original pins. With a cross-cut fissure bur drill the backing to the depth of the platinum pins, cut a slot to and including the other pin, and with a cone-shaped bur countersink the slot on the lingual side. Now select a suitable facing, the pins of which will pass into the slot. Remove the facing, and with a flat, wedge-shaped instrument pressed tightly between the pins and close to the porcelain, bend the ends of the pins together, and with a file flatten the pins slightly where the ends meet, so that a small piece of No. 18-k. solder can be laid upon them.

Then lay the facing on a piece of asbestos, and with a mouth blowpipe gently heat up and solder the pins together, thus forming a staple, which when the facing is in place will enter the slot and extend into the countersunk portion. The latter is then filled with quick-setting amalgam and the repair is completed.

Dr. G. V. I. BROWN, Milwaukee, Wis.
 "Cleft Palate—Surgical."

Two operations for the surgical closure of cleft palate were performed. One of the cases was that of a boy, two years of age, with a large opening in the hard palate that still persisted after two previous unsuccessful operations for the closure of congenital cleft of the hard and soft palates. The borders of the opening in the hard palate were freshened, and all the tissue loosened from it, including the periosteum as well as the overlying structures. Incisions were made along the alveolar borders of the palate, and the intervening tissue drawn together and sutured in the center. The final result as reported by the physician in charge was entirely successful.

The second patient was a little girl, two and one-half years of age, with a fissure in the soft palate extending nearly through the hard palate, the alveolar portion in front being intact. The same operation as described in the previous case was performed successfully with the complete closure of the fissure. This patient was removed from the hospital the day after the operation and taken to her home in another city. Notwithstanding the fact that conditions for treatment were thus made extremely difficult, a recent report from the physician in charge is entirely satisfactory, a result that under the circumstances is largely due to the faithful post-operative care of Dr. M. C. Smith.

Dr. GEORGE C. AINSWORTH, Boston.
 "A Compound Bicuspid or Molar Filling. Using the Matrix and Soft or Semi-cohesive Gold at the Cervical Wall, Extending Up Two-thirds of the Filling, and Finishing with Cohesive Gold under the Mallet."

The advantages of this method are: Much saving of time and strain upon the part of both patient and operator, besides a far better insurance against future caries at the cervical wall, by virtue of the soft gold used at the points most liable to recurrent decay. It also leaves that part of the filling ordinarily most difficult of access to the finishing process, well-nigh finished, requiring scarcely more than a careful burnishing at the cervical wall. This method has been his constant practice for more than twenty years, during which time he has become more and more convinced that a proper matrix correctly applied is one of the greatest assistants in modern dentistry.

Dr. C. D. BEEDLE, Leominster. "A Bridge, Using S. S. White or Justi Diatoric Teeth for the Facings, and Gold Inlays for the Abutments."

A plaster impression and bite of the teeth are taken with the inlays in place. The inlays are removed from the teeth and placed in proper position in the impression, and a cast made. A suitable tooth is selected, and 22-k. gold, No. 32 or 34 gage, is burnished to the back and into the opening of the diatoric tooth. The inlays are removed from the cast, and slots drilled in them at right angles to the long axis of the tooth, as near to the cervical edge of the inlay as is consistent with strength, and a flat platinum and iridium bar is fitted to the slots. The inlays and bar are then replaced on the cast, and the teeth and backings are adjusted and fastened with sticky-wax. The whole piece is then removed; the inlays and teeth are taken from the bar and backing, which are invested and soldered. The inlays and bar are cemented in place. When hard, the surplus cement is removed and the teeth are cemented to the backing.

Dr. GEORGE T. BAKER, Boston. "Orthodontia, Showing Appliances in the Mouth."

A patient was shown with appliances in position for the correction of positional irregularities of the teeth. The patient

was a boy, thirteen years of age, and the malposition was attributed to three causes: (1) Mouth-breathing, due to adenoids and enlarged tonsils; (2) too long retention of the deciduous teeth; (3) a habit of biting the lower lip.

These combined causes had resulted in an abnormal protrusion of the upper incisors, a contraction of the maxilla and mandible, and a developing retrusion of the lower teeth. The adenoids and tonsils had been excised, and normal breathing was restored. The lower second deciduous molars had been extracted to make way for the bicuspid, which soon erupted. Appliances were made of German silver spring wire for both upper and lower teeth (Jackson). Thus the arches were spread, the upper incisors retracted, and normal occlusion restored. Plaster casts were shown representing the mouth both before and after the treatment. Attention was called to the clean and healthy condition of the mouth, the absence of all inflammation, and the ease and comfort with which the appliances were worn, being easily removed for the purpose of brushing the teeth.

Dr. C. EDSON ABBOTT, Franklin. "Porcelain Inlay in Approximo-incisal Restoration in Anterior Teeth, with Special Reference to Strength."

Patient, Dr. K. Palmer, Mass. The cavity, a large approximo-incisal one in an upper right central, including the lingual pit and embracing one-third of the width of the tooth.

Cavity preparation. The tooth and neighboring territory were thoroughly cleaned and the mouth was sprayed. All decay was removed with sharp burs. A flat cervical seat was obtained with the square fissure burs. A deep depression was cut in the tooth throughout its extent, so as to retain the inlay by a large tongue of porcelain extending throughout the cavity. The margins were shaped and finished with finishing burs, stones, and disks to the utmost smoothness, and at right angles with the tooth-surfaces.

Matrix formation. The matrix was prepared by forcing the center of a large piece of annealed platinum foil, 1/1000,

into the bottom of the cavity with a ball of cotton. The cotton was removed, and the matrix was held in place with a strip of rubber dam and burnished to an accurate fit. The final burnishing being direct on the platinum foil at the margins, made it thinnest at that point, thus giving the best possible joint. The matrix is held firmly with the fingers over the margin, the excess foil is bent free, and the matrix teased out.

Baking. The first bake was a thin film of yellow foundation body; the second bake was of the same material, and restored the dentin of the tooth in color and shape. Two bakes of No. A enamel body finished the inlay, the contour being determined by geometrically projecting the tooth-surfaces shown by the matrix.

Cementation. The matrix was peeled off the moistened inlay, and tooth and inlay undercut with wheel burs and carborundum disk, sprayed and dried, and the inlay cemented in position with creamy Harvard special inlay cement of the same shade as the enamel. The inlay was held firmly in place with springy steel instruments until the cement had hardened, and paraffin was then flowed over the completed operation.

The special point of novelty in the operation is the retention of the matrix in the cavity with strips of rubber dam, which hold it firmly against the margins at all points, preventing tears and distortion, and allowing perfect vision of the cavity, and a slight rounding of the incisal margins of the tooth and inlay with disks before setting. The cavity was made with a joint square across the cutting edge, and with a slight half-round groove between the enamel plates made by a small finishing fissure bur held parallel to the long axis of the tooth. All incisal margins being rounded, the blunt margins resist wear, and although in appearance like the tubercle of a tooth, yet show no break in the continuity of appearance, and in addition the joint is somewhat sheltered from direct stress.

I would recommend a trial of the principle of the blunt margin method in margins exposed to the stress of mastication.

Dr. I. J. WETHERBEE, Boston. "Tin and Gold."

Dr. Wetherbee's clinic consisted of a combination tin and gold filling in a mesio-occlusal cavity of a bicuspid tooth.

NATIONAL DENTAL ASSOCIATION.

Tenth Annual Meeting, Atlanta, Ga., September 18-21, 1906.

General Sessions.

TUESDAY—*First Session.*

THE tenth annual meeting of the National Dental Association was held at Atlanta, Ga., September 18 to 21, 1906, in the ball-room of the New Kimball House.

The first general session was called to order at 10 o'clock Tuesday, September 18th, by the president, Dr. M. F. Finley, Washington, D. C.

Rev. Dr. Junius W. Millard, Atlanta, Ga., invoked divine blessings on the deliberations of the association.

The President then introduced Governor J. M. Terrell, who delivered the address of welcome to the association.

Following the address of the Governor, the President of the association, Dr. M. F. Finley, introduced Dr. D. D. Atkinson of Brunswick, Ga., who delivered an address of welcome on behalf of the dentists

of the state of Georgia; at the close of which,

The response to both addresses on behalf of the National Dental Association was made in felicitous terms by Dr. B. Holly Smith of Baltimore.

At the close of Dr. Smith's address the Executive Council made a brief report through its chairman, Dr. H. J. Burkhart of Batavia, N. Y., upon some matters of business routine and announcing the reading of the President's address, to be followed by the reading of a paper by Dr. C. S. Butler of Buffalo, N. Y., as the program for the meeting as then in session. This report of the Executive Council having been formally adopted,

Dr. Frank Holland, Atlanta, Ga., vice-president from the South, was called to the chair, and the president, Dr. M. F. FINLEY, read his annual address, as follows:

PRESIDENT'S ADDRESS.

The pleasant privilege of welcoming so large a number of professional brethren to this the tenth annual meeting of the National Dental Association is a source of extreme gratification to me.

The warm-hearted greetings from the chief executive of this state and from a local professional brother, voicing the sentiments of this community, which ranks so high commercially, politically, socially, and educationally, ought to inspire us to be faithful and earnest in our work while here, to measure up to the full standard of our obligations in seeking out the truths of nature and science and promulgating them for the benefit of humanity. Your very presence means that such will be the case, for only those devoted to the best interests of their profession will make the sacrifices necessary to attend such gatherings.

I congratulate you all upon this auspicious occasion in that so many are here, and that so many are to take part in the program of papers and clinics; such labors indicate a genuine love for the profession of dentistry, the profession you have chosen for your life-work and which is surely worthy of your best efforts.

On behalf of the National Dental Association I take great pleasure in extending to you all a most hearty welcome and a cordial invitation to participate in the deliberations of this meeting. This occasion is one that I cannot let pass without again voicing the strongest sentiments of appreciation of the honor with which this great association invested me in Buffalo last year, and without again sincerely thanking you for the confidence thus manifested. For twenty-seven years my name has been on the rolls of this association and its predecessors, and thus it has been my privilege to know the great lights in dentistry of that period—which knowledge has been to me a constant source of inspiration and pleasure. This association and its predecessors have made enviable records in history through the efforts put forth in their name.

With these influences as incentives it has been my earnest desire and utmost endeavor to fulfil the obligations of this high office with truth and justice as guides. I realize the limitations placed upon human individual effort, and, so doing, have sought advice and counsel from those more experienced before taking action upon any matter which came to my notice.

Since the Buffalo meeting a series of important events have occurred demanding deliberation and action to which I will now invite your attention. The first matter requiring consideration was in consequence of the prevalence of yellow fever in the ports of the southern states last summer and fall, and a request came from members and officers of the association for a change of date of the Atlanta meeting to avoid what seemed a danger for a meeting to be held in the South in September. A postal-card vote was suggested to make the date of meeting in October instead of the date fixed by vote of the association at Buffalo.

To remove the necessity for a change of date, which is always so disastrous to the attendance on such occasions, I determined to seek information and advice from the Public Health and Marine Hospital Service, and forthwith wrote to the

Surgeon-general of that service and received the following reply:

TREASURY DEPARTMENT, WASHINGTON,
November 27, 1905.

DR. M. F. FINLEY, President National Dental Association, Washington, D. C.

Sir,—The Bureau is in receipt of your communication of November 25, 1905, requesting to be informed, in the interest of the dental profession, whose National Association meets in Atlanta, Ga., next September, what the probabilities are for a return of yellow fever next summer in the ports of the southern states.

In reply, you are informed that while there is always a possibility of a recrudescence of the disease, the Bureau does not regard a recurrence of the fever as a probability, and measures are now being taken and will be continued throughout the winter to prevent such a contingency. While not assured of the success of such measures, the Bureau has faith in their efficacy.

Respectfully,

A. H. GLENNAN,
Acting Surgeon-general.

This reply was communicated to those who had written me about changing the date of the meeting, and was the assurance needed to quiet anxiety and settle that point.

Another matter of great import was the appalling disaster which befell San Francisco and other near-by cities of California when the earthquake and fire made such havoc.

Communications both by wire and by mail reached me from the chairman of your Executive Committee and Executive Council, suggesting a contribution from the funds of this association to aid our suffering professional brethren. After considerable correspondence with other officers of the association to ascertain the amount of funds available, an order for \$250 was drawn on the treasurer, to be sent to Dr. Leander Van Orden, San Francisco, secretary of the Dentists' Relief Committee, to assist the distressed in our profession. Indorsement by the association of this action is hoped for. Also, after consultation among the members of the Committee of Fifteen of the Fourth International Dental Congress, it was de-

termined to send from the funds of that organization the sum of \$750 for the same object, viz, relief of earthquake sufferers in California. Following is Dr. Van Orden's letter of acknowledgment:

2417 WASHINGTON ST.,
SAN FRANCISCO, CALIFORNIA,
May 22, 1906.

DR. M. F. FINLEY, Treasurer Fourth International Congress, 1928 I st., N. W., Washington, D. C.

Dear Dr. Finley,—Please accept our grateful acknowledgment of the receipt of the most generous gift, \$750, through your hands, from the Committee of Fifteen of the Fourth International Dental Congress. It comes most opportunely, for we have exhausted the money so generously sent from Chicago. While our men are bearing themselves bravely in the face of disaster, we fear that there are some cases of serious distress, which we hope to justly seek out. We will be glad to try to limit the benefaction to ethical practitioners, though every class of us must be impressed with the deep-down satisfaction that comes only from generous, unselfish fraternal co-operation. We can only hope that the great geographical distance of California will be offset in the future by the short road of fraternal effort, and that our memories may be long ones. We will gratefully acknowledge the donation from the National Dental Association.

With personal appreciation, I am

Yours sincerely and hopefully,

LEANDER VAN ORDEN.
Sec'y Dentists' Relief Committee.

Again: Information was brought to my attention, in rumors, of a determination to supersede the National Dental Association by organizing another association of a national character, or reviving one of the old associations to which the National Dental Association succeeded.

After careful thought, consultation, and advice, it was determined to incorporate the National Dental Association as successor to the American Dental Association and the Southern Dental Association, in order to protect this organization in its rights and perpetuate it for the good it had done and might hereafter accomplish. Herewith is the document setting forth that action:

**CERTIFICATE OF INCORPORATION OF THE
NATIONAL DENTAL ASSOCIATION.**

The undersigned, MARK F. FINLEY, J. H. LONDON, and W. N. COGAN, all being of full age, citizens of the United States, and residents of the District of Columbia, desiring to associate themselves and the present members of the unincorporated society known as the "National Dental Association" (successors of the unincorporated societies known as the "American Dental Association" and the "Southern Dental Association"), in the formation of an incorporated society, for the purposes and objects hereinafter set forth, do hereby certify as follows:

First: The name by which this incorporated society shall be known in law shall be THE NATIONAL DENTAL ASSOCIATION.

Second: The term for which this society is organized shall be perpetual.

Third: The particular business and objects of this society shall be to cultivate the science and art of dentistry and of its collateral branches, to elevate and sustain the professional character of dentists, to promote among them mutual improvement, social intercourse and good feeling, and, collectively, to represent and have cognizance of the common interests of the dental profession.

Fourth: The number of its Trustees, Directors, or Managers, for the first year of its existence, shall be sixteen (16), who shall be divided into an Executive Committee, consisting of nine (9) members, as follows, to wit:

J. D. PATTERSON, of Kansas City, Missouri.
C. N. JOHNSON, of Chicago, Illinois.
H. B. McFADDEN, of Philadelphia, Pennsylvania.
V. H. JACKSON, of New York, N. Y.
C. J. GRIEVES, of Baltimore, Maryland.
W. N. COGAN, of Washington, D. C.
C. S. BUTLER, of Buffalo, New York.
G. V. I. BROWN, of Milwaukee, Wisconsin.
T. P. HINMAN, of Atlanta, Georgia.

And an Executive Council, consisting of seven (7) members, as follows, to wit:

H. J. BURKHART, *Chairman*, of Batavia, N. Y.
J. Y. CRAWFORD, of Nashville, Tenn.
CHAS. McMANUS, of Hartford, Conn.
F. O. HETRICK, of Ottawa, Kan.
E. K. BLAIR, of Waverly, Ill.
M. F. FINLEY, of Washington, D. C.
A. H. PECK, of Chicago, Illinois.

Fifth: It is hereby particularly provided that all present permanent members of the unincorporated society known as the National Dental Association shall be considered as permanent members of this incorporated society, known as the National Dental Association, and shall be entitled to all the privileges

of the class to which they belong, without further action.

Sixth: The above-named incorporated society shall have no capital stock.

Seventh: The present Constitution and Rules of Order of the unincorporated society known as the National Dental Association are hereby adopted as the Constitution and Rules of Order of the incorporated society known as the National Dental Association, in so far as the same are not in conflict with any law now in force enacted by the Congress of the United States.

Eighth: The officers of this incorporated society shall be the present officers of the unincorporated society known as the National Dental Association, and all committees elected or appointed by the said National Dental Association, at its last annual meeting, held in the city of Buffalo, state of New York, on the 25th, 26th, and 27th days of July 1905, shall be considered the officers and committees of this incorporated society known as the National Dental Association, until their successors shall be elected or appointed, in accordance with the Constitution and By-laws.

In witness whereof, we have hereunto set our hands and seals this fifth day of March, A. D. 1906.

(Signed) {	MARK F. FINLEY.	[Seal.]
	J. H. LONDON.	[Seal.]
	W. N. COGAN.	[Seal.]

CITY OF WASHINGTON, } ss:
DISTRICT OF COLUMBIA. }

I, Mason N. Richardson, a Notary Public in and for the District of Columbia, do hereby certify that Mark F. Finley, J. H. London, and W. N. Cogan, personally well known unto me as being the parties who executed the foregoing and annexed Certificate of Incorporation of the National Dental Association, personally appeared before me, in said District, and acknowledged the same to be their act and deed, and the act and deed of each of them.

In witness whereof, I have hereunto affixed my official seal, this fifth day of March, A. D. 1906.

(Signed) MASON N. RICHARDSON,
[Seal.] Notary Public, D. C.

Further: False criticisms of the work of one of the most important committees of this association were made, published, and circulated, in an effort to defeat the very purpose for which this committee was called into existence and for which it had so assiduously labored.

Resolutions have been passed by this association directing that all matters pertaining to the work of legislation should be transacted through this same committee. Had those criticisms been left to stand, and those making and circulating them left to pursue their plans, the work of this important committee, which had been ably supplemented by some of the best men in the profession and by the authorities of the best educational institutions of the country, would have been nullified and the profession's dignity belittled and degraded.

Consequently, after due consideration and consultation a special committee was appointed to look into and consider all questions involved. This special committee has prepared a report, and at a time to be designated it will be presented to the association.

At the union meeting of the Maryland State Dental Association and the District of Columbia Dental Society held in June, a paper was presented on "Pharmacopeial Revision," by Edward Hoffmeister of Baltimore, which contained a suggestion that the National Dental Association consider the advisability of sending delegates to the next convention for revision of the U. S. Pharmacopeia.

This suggestion seemed to me a good one, and to further the project I wish to present a few items of history. In 1817 Dr. Lyman Spalding of New York city submitted to the Medical Society of the County of New York a project for the formation of a National Pharmacopeia. The first general convention for formation of a National Pharmacopeia assembled in Washington, D. C., January 1, 1820, and published the Pharmacopeia adopted at that convention on December 15, 1820, since which time, at regular intervals, revisions have been made. The membership of the Convention for Pharmacopeial Revision is composed of representatives from the Medical Departments of the Army, Navy, and Marine Hospital Service; medical societies and associations, medical colleges and universities; pharmaceutical associations, colleges and universities of pharmacy.

The dental profession has so far advanced, and is so interested in the questions to come before this convention of revision, that I determined to write to the president of the U. S. Pharmacopeial Convention to ascertain if delegates would be received from the National Dental Association in the next Pharmacopeial Convention. Following is a reply:

LONGPORT, N. J.,
July 25, 1906.

DR. M. F. FINLEY, President, 1928 I st., N.W.,
Washington, D. C.

Dear Sir,—Your letter of July 12th has been handed to me for reply, Dr. H. C. Wood, president of the U. S. Pharmacopeial Convention being out of town on his vacation at Rangely, Me.

The next convention for the revision of the U. S. Pharmacopeia will assemble in the city of Washington on the first Monday of May 1910. My personal opinion is that the National Dental Association delegates would be given a welcome at the convention, with the privileges of the floor. I think it would require a resolution passed by the convention to receive the delegates as full members. I would advise writing to the president of the convention, Dr. H. C. Wood, about January 1910. He will probably authorize the appointment of delegates from your body.

Very truly yours,

JOSEPH P. REMINGTON,
Chairman Committee of Revision.

I would suggest that this association seriously consider this opportunity and prepare to send delegates to the convention.

Since our last meeting the Transactions of the Fourth International Dental Congress have appeared, and are a glorious monument to the credit of this association, which authorized and fostered that congress. The publishers should also be congratulated on such splendid work as is manifest in the make-up of those three volumes.

A full and final report of the Committee of Fifteen, which had in charge the organization and conduct of this great Fourth International Dental Congress, will be made at this meeting, every detail of the work intrusted to that Committee having been completed.

ARMY MEDICAL MUSEUM AND LIBRARY.

Especial attention is invited to the valuable exhibit pertaining to dentistry, in both the Army Medical Museum and Library, and again, I would urge every member of the association to make contributions, to this vast storehouse, of specimens which are of value and which otherwise may be lost to the profession—where they will be made of permanent benefit by their proper arrangement, display, and care, and will be a source of education, and will also in a most distinct way enable dentistry to make a record comparable to that of medicine.

The record already there is due to the earnest efforts of the committee of this association, whose hands should be strengthened by more and better support from the entire membership. I would suggest a revival of the effort by this association to induce Congress to appropriate for and establish the position of dental assistant curator in that institution. This plan was tried several years ago, and, with proper effort now, it is my opinion that our profession would be recognized at this time by Congress to that extent. Such a position would afford wonderful opportunity for research work in many directions, and annual reports could be made which would stimulate and arouse zeal in the profession.

In the National Museum, an institution adjoining the Army Medical Museum and Library, there is also great opportunity for research work in both medicine and dentistry, but advantage is not being taken as it should be by the professions, of the available material the government is there collecting and arranging. Through an introduction by Dr. Bogue to an official there, it has been my privilege to note the possibilities for enabling valuable knowledge to be dug out of those collections, in a direction other than the course which those in the employ of the government are now pursuing. It is my suggestion, also, that this association establish a chair or found a professorship in research work in these government institutions, and make it permanent by appropriating a fixed sum

therefor, believing that in so doing we will make a record to the everlasting credit of our association and our profession. Repeatedly have the members of the dental profession in Washington, D. C., conducted members of this and other societies through the above-mentioned museums and library, and in the interest of progress have endeavored to spread as broadly as possible the knowledge of the usefulness of the collections there accumulating.

COMMITTEE ON HISTORY.

This association is to be congratulated on the success which has attended the efforts of its Committee on History, which has, in the interim since our last meeting, offered to the members a volume of valuable historical interest to the profession. The membership should show their full appreciation of this committee's efforts, by quickly responding to the appeal which has been made for funds to publish this work. In fact, better and more unanimous and more unselfish support should be given to every committee of this association in their work if true progress is to be made in dentistry, and if that progress is to accomplish the most good that can be made of it. Your committee on History further states that when this first volume is successfully published, a second and companion volume will be issued, treating of the more modern aspect of dentistry. How essential, then, that we come forward generously and place the sinews of war in the hands of our hard-working Committee on History.

COMMITTEE ON ORAL HYGIENE.

I cordially indorse the work of the Committee on Oral Hygiene, which has labored assiduously since its first establishment. A very interesting and valuable presentation of material for your consideration will be made at this meeting, and a solution is offered to the problem which has been uppermost in the minds of the leaders of the work of this committee, by a resolution to be offered and which was placed on the program

that all might see it and be favorably impressed by it. The resolution is as follows:

RESOLVED, That the National Dental Association authorize their Committee on Oral Hygiene to formulate and publish a "first edition" of a treatise on Oral Hygiene for the public; the total cost of compilation and publication to be not more than \$250.

I recommend that this resolution be adopted after the Committee on Oral Hygiene has made its presentation, as I think it is a step in the right direction which has too long been delayed. The chairman of this committee has offered to undertake the compilation of this treatise for love of his profession, which simply leaves the cost of publication to be borne by this association.

COMMITTEE ON ARMY AND NAVY LEGISLATION.

The association is more or less familiar with the work of this committee, which was first appointed at Omaha in 1898, and which has labored in season and out to obtain a proper recognition by the government in its military and naval services of the profession of dentistry, in the establishment of a dental corps with rank and right of promotion and retirement. A full and succinct account of the efforts of this committee will be presented to you in the report of its chairman.

DENTAL JOURNAL.

If a plan shall develop at this meeting to start a journal of the association, a consummation devoutly to be wished, I would favor the idea of our making a separate contribution of one dollar, in addition to the dues of the association as they now stand, for the support of the journal. This would instantly place a considerable sum at the disposal of a committee of publication, and would also make a legitimate list of subscribers to aid in securing postal concessions. Further, it would be my idea that the journal should be entirely owned and managed by this association, with no partnership arrangements with other associations or societies.

SECTIONS.

The question of how best to arrange the work of the sections to meet the demands of our membership has been a serious proposition for a good many years, and has been alluded to in the annual addresses of former presidents, and has been handled by the committees of revision of the constitution many times. It certainly would be advantageous if the opinion of this association could be made unanimous as to a final plan of procedure. To avoid some of the objections of the simultaneous meetings of the three sections, your Program Committee this year ask your co-operation and earnest assistance in the trial of the scheme of one section at a time, and the sections alternating instead of being in continuous session, thus avoiding the possibility of one of the sections not being reached at all, as was the case in the American Association.

I will repeat what appears in the announcement of the program. It is deemed wise by the Program Committee—in consequence of the seemingly prevailing sentiment that all papers be read so that the entire membership shall have an opportunity to hear and discuss them—to so arrange that only one section will be in session at a time; and, to make the plan feasible, an appeal is made, first, to essayists, to make their papers concise, crisp, and limited in length; secondly, to all those taking part in the discussions, to make them concise and crisp—to the end that the entire program may be carried out, thus giving to those who have been sufficiently interested to prepare papers an opportunity to read them and have them creditably discussed.

To make the discussion more general and give it direction, a synopsis of several papers was printed in the program for the benefit of those most interested in the subjects handled, and I would recommend that it be the policy of the association in the future to print a synopsis of all papers in the program. There will be sufficient time allowed for carrying out the program, so that each section will

have two sessions of at least three hours' duration, which should be ample time to compass the work mapped out if the members will be prompt in attendance, and will show an interest and make concerted effort to assist the committee.

Just here let me acknowledge with extreme gratitude, the very generous and hearty assistance and support of section and committee officers in securing and arranging the scientific matter for the program, and the same character of assistance and support from the general officers and committees, in arranging the details of preparation for carrying out the work of the convention, and likewise from the membership in all that has been done in the interest and welfare of this meeting of the association—all of which will help toward the general elevation and upbuilding of the profession in its various ramifications.

MEMBERSHIP.

In the interest of increasing the membership of this association, which is sadly in need of arithmetical or geometrical progression in order to make the figures commensurate with the number in the profession which it represents, I would recommend a change in Section I of Article IV of the Constitution, which reads, "Any permanently organized state dental society may send one for every six of its active members as delegates," etc., by eliminating the words "one for every six of"—making it read, "Any permanently organized state dental society may send its active members as delegates," etc. I suggest this in the belief that it will stimulate an interest on the part of different state societies in this association. There is a committee of this association on state societies, and it would seem to me that with the limitation removed as to representation from those societies, there might be some rivalry engendered, which would encourage an increase in delegates; and I would further suggest, that a prize in the shape of a medal or certificate be offered to the state society sending the largest number of new members as delegates each year.

It is with very great regret that I note the absence of so many of our members because of unfortunate circumstances—such as sickness, calamities by earthquake and fire, and the wrecking of financial institutions—who, but for the interference of these untoward events, would be among us battling for the success of this meeting. I can but note with sadness and regret the removal from our midst, by Divine Providence, of so many of our faithful, conscientious, and devoted workers, whose remarkably lovable traits of character displayed upon all occasions were so lavishly manifested toward those who were fortunate enough to enjoy the acquaintance of these departed ones. I must mention by name two at least, with whom I have been so intimately associated for a goodly number of years in the work of this body—Chas. C. Chittenden and J. A. Chapple, as to whom it can be justly said that we are each of us better for having known them. The latter of these we had all looked forward to the pleasure of meeting at his own home, where alone the true genius of the man was displayed to its full capacity. We here offer our sincere tribute to all those who have left us since our last meeting, and deposit upon their tombs a wreath of perpetual remembrance; and we also hope that through spirit communication they may be made aware of the genuine manifestations of regret at the loss those who remain have sustained.

But, to come back to the duties before us, we are assembled for a specific purpose, each with a task assigned—to do the utmost for the elevation and upbuilding of the profession of dentistry. By always maintaining the truth and actuated by motives of justice, striving to conform to the tenets of the code of ethics, in the hope of seeing this profession, through its membership, constantly moving upward and onward in the scale of development, are we encouraged to the belief that right will prevail, that success will attend our efforts, and that dentistry will attain to the high ideals set for it by the most sanguine devotees in the profession.

Dr. B. HOLLY SMITH. I move you, sir, that this address be referred to a commit-

tee of three to report to the association on the recommendations therein contained.

The motion was carried.

Dr. Holland appointed as such committee the following: Dr. B. Holly Smith, Baltimore; Dr. John I. Hart, New York, and Dr. H. B. Tileston, Louisville.

Dr. Finley resumed the chair and introduced Dr. CHAS. S. BUTLER of Buffalo, N. Y., who read a paper entitled "The Educational Problem," as follows:

THE EDUCATIONAL PROBLEM.

I have prepared this paper on the Educational Problem at the earnest request of the chairman of Section II, and in its presentation shall offer for your consideration four propositions, the combination of which, in their working out, is designed to effect a complete though perhaps not a perfect change in our entire educational system.

(1) The abolition, by gradual absorption and elimination, of all our present schools, and the substitution therefor of departments in strong universities, with faculties selected by the profession itself, and for which each teacher shall be chosen with due consideration as to his known fitness to fill the position he is to occupy.

(2) The abolition of state examining boards as being superfluous and of doubtful utility in any system of professional education.

(3) The creation of a national commission with plenary powers in regard to location of the schools, curriculum of study, and entrance requirements, as well as general oversight of their affairs.

(4) The diploma of said schools, when granted in course and indorsed by the national commission, to be accepted as a license to practice in any state or territory of the United States.

When, in 1839, men desiring facilities for adequate instruction in dental subjects were denied admission to medical schools, and their suggestion of a dental science was spurned with contempt as being beneath the dignity of men in charge of those institutions, the great science of medicine and surgery was set

forward to a degree not easily understood by any at that time, and scarcely realized or appreciated by us today; for it is to the enforced establishment of separate and independent schools for teaching dentistry that is due in large measure the development of microscopy and the marvelous advance in our knowledge of histology, pathology and kindred sciences, as well as the wide application of antiseptics—for it was men engaged in the study of dental sciences who led the way and gave the impetus to their development. To it also may be traced the wide introduction into the curriculum of our public schools, of a system of manual training, the application and thoroughness of which is preparing as never before a generation of youths to enter upon a life-work of usefulness and profit. But great and far-reaching as these have been, its greatest influence, undoubtedly, has been in leading to the development of a system of dental instruction, peculiar to itself and in some ways not surpassed in efficiency in any other field of intellectual activity.

But notwithstanding its efficiency and apparent thoroughness, it is a serious question whether its limit of proficiency has not been reached; whether, indeed, there has not been a marked retrogression in the results of its operations during the past five years or more. To one who has been a close student for more than a quarter of a century, and always deeply interested in everything pertaining to our educational matters, this seems to be true; or to state it in another way—that our entire educational fabric is falling apart under the stress of its own weight. But, be this as it may, it certainly is true that the time has fully come when the profession itself should lay hold of this whole question seriously and with a determination to put our educational affairs on a plane relatively as high as that of the other learned professions. To do this some radical change of methods must needs be adopted; the number of the schools should be gradually reduced, and the quality and character of those remaining greatly enhanced. This may be done in two ways, but preferably, perhaps, by a gradual elimination of those schools now

in existence by their combination with and absorption into departments in strong universities centrally located in different sections of the country, thoroughly established and well grounded in the true university spirit, and in the midst of large and prosperous communities.

Those of you who have observed closely the trend of educational matters during the past half-dozen years must have been impressed with two things—first, the inability of our present system to meet the demands of the profession; and secondly, the unmistakable tendency toward university departments in the schools themselves. That these things are observable is matter for congratulation, as at least showing a disposition on the part of the schools and of the profession to be dissatisfied with present conditions, and is a healthful and encouraging sign. It is a new spirit with us, and should not be repressed or discouraged; on the contrary, we should welcome it and seek to direct its energy. It does not follow that because men are dissatisfied that they are disaffected. All reforms and changes are awakened by dissatisfied men, but by disaffected men, never. This trend toward university departments, therefore, awakened by men dissatisfied with present conditions, is evidence of their own earnestness, and is readily explained and easily understood when the alliance is sought with universities where all of the departments are under one general management, where all of the teachers are employed at fixed salaries, and where the funds are used for the symmetrical development of the whole university.

The advantages growing out of an alliance of that character are so obvious that no institution concerned at all in its own welfare could afford to neglect it. But if it were possible for all our schools to be thus situated, which of course it is not, even then not all that is needed by the schools or is demanded by the profession could be realized; so that, while we may congratulate ourselves on this manifestation of a desire for better things, we cannot rest satisfied with this alone, even though it does offer advantages not easily obtainable by schools otherwise

situated. The community of interests necessarily existing in the several departments of a university—the interdependence of these departments, but more particularly the “fraternity spirit,” which means so much and which is so difficult to define or understand, and which can be developed in its highest and best sense only amid such surroundings, are some of the indispensable conditions necessary in the building up of schools of the highest efficiency and usefulness. Educationally speaking, we do not appreciate at its full value the true fraternity spirit. This is not strange; we see so little of it, for it is only to be found amid real university surroundings.

A recent writer in one of our magazines, speaking of Oxford, said: “This fraternity spirit is one of the greatest benefits to be derived from this old university. While it is not tangible or visible, nevertheless it is a living reality, and its potent force can be readily felt. It is a subtle influence, which enthuses one and gives him that true love of knowledge which at once marks him as a scholar. It wears down rough positiveness, softens the severity of prejudiced criticism, and cultures and refines thought—that is, true intellectual thought.”

Under our present system, if there be any one thing more pronounced than another, it is that “rough positiveness” here referred to, for our entire educational training, as well as our professional practice, is made up almost wholly of dogmatics, and it is only by widening our intellectual horizon, through the medium of a truer appreciation of the value of the interdependence one upon another of the various departments in great universities, that we as a profession can hope to grow.

No profession can live unto itself alone, and continue to live. If it try to do so it will inevitably become, sooner or later, a dying profession. It must yield something for the general good, and it cannot retain the good it has already accomplished without striving for more. “In the lives of professions as in the lives of men, there is no level place, nor is there any brake to hold them at rest on

the slopes where they are set." They must climb or they must slip. To mount or to fall, to grow or to decay, to grasp more of the spirit of progress or less, more of personal self-sacrifice or less—these are matters of choice; but we must choose, and upon the choice we make will depend, in large measure, the future advancement or certain decay of our profession.

The growth of a profession, like the growth of general education, is a part of development of the whole intellectual life of the nation; and that nation grows best which harmoniously and aggressively identifies itself with the educational needs of its people. It is in the recognition of this law of the intellectual growth of the nation—or rather, the recognition of the needs of a people in their intellectual development—that the foundations of our universities are laid; a fact which we, though one of the younger of the professions, should be quick to recognize and appreciate.

Other and very marked advantages accruing to these departments would be found, not only in the curtailing of the number of schools, but also in the superior equipment, enhanced facilities by reason of location, environment, etc., and not the least of all in the concentration of patronage, thereby affording advantages not usually recognized, namely, in the stimulus to both teacher and pupil that comes with large numbers. It must always be remembered that it not infrequently happens that the very best work in any school is done by the individual teacher with the individual pupil, but yet it should not be forgotten that the stimulus and encouragement that come with well-organized and flourishing institutions, where all the activities are running at flood tide, are far greater than with small, struggling, and oftentimes poorly equipped schools, no matter how high their ambitions or how honest their intentions. But the great problem to be worked out in this proposed change is not the recognition and utilization of the advantages accruing from its adoption, but how best to appropriate and assimilate all that is worthy and of value in our present schools. They all have vested interests

which must be conserved, and of which each and all will be required to yield something for the general good. Just how this is to be accomplished is matter for future consideration. It is no part of the purpose of this paper to discuss that phase of the question, beyond saying that a fair and a workable solution of it is certainly within the bounds of reasonable probability.

(2) *As to the abolition of State Examining Boards.* In any system of professional education, examination, as by our examining boards, placed upon the products of the schools from without, is unnatural, indicating lack of confidence, if not actual distrust and condemnation. The examination and oversight by the profession should be placed upon the schools themselves, and should be so effective that it would be impossible for vicious and incompetent men to be graduated. This would at once eliminate any possible or fancied necessity for state examining boards, the existence of which has been a direct censure upon our entire educational system. These boards, through the influence of their national association, have done much to lower the standards and to bring the dental degree into disfavor both at home and abroad, besides harassing many of the schools, without accomplishing any useful purpose.

To some this may seem like a harsh criticism, and particularly so when we recall the many earnest, unselfish, and devoted men who have been active in the work of that association, and who have always intended and desired the very best, both for dental education and for the profession itself. The criticism is not of the men, but of the false conception on which the association was founded, and the fancied functions it was assumed that it had to perform. It is possible that had the association confined its efforts to the work of organizing and building up the state boards, perfecting and unifying methods of examinations, and in ways that were legitimately possible encouraging and assisting the schools in the real business of education, instead of attempting to dictate as to their internal man-

agement and to prescribe their standing and reputability, its field of usefulness might have been enhanced, education advanced, and its formation and existence seemingly justified. I say "seemingly justified," by which I mean under our present system.

But all this as touching the National Association of Dental Examiners has really no place in this discussion, and I have introduced it here only for the purpose of making clear the unscientific and unbusiness-like conditions under which our students are trained.

(3) *As to the creation of a National Commission.* The desirability of such a commission and something of the functions it might legitimately assume have already been hinted at, and it is only necessary to point out specifically its special field of usefulness to make its importance, in any system of education such as ours, at once apparent. And first of all—and this undoubtedly would be its greatest work—would be the preparation and adoption of uniform equipments, uniform preliminary requirements, uniform curricula of study, and uniform intermediate and final examinations as to proficiency—this for all the schools, and as a basis upon which to begin the erection of a modernized system of education that would be commensurate with the needs of our profession. To these also would be added a general superintendence or oversight of the schools, with authority to veto unworthy faculty appointments, and the right of review of all graduation examinations, etc.

(4) *The diploma, when indorsed by the National Commission, to be accepted as a license to practice in any state or territory of the United States.* This would at once invest our degree with a dignity and value not possessed by any other profession. It would also prepare the way for the acceptance of a universal degree, and would become a strong, stimulating force in building up a system of education for our students which should equal that of any of the learned professions, and at the same time widen the scope of individual usefulness of all our members.

The training of the human mind,

whether in primary or secondary education, has ever been deemed the highest duty and privilege of man, and the greatest intellects and first scholars of every age have not deemed it derogatory to their dignity to devote themselves to its consideration, and have ever held it to be the highest duty of the state and nation to provide liberally for the care and development of the people in their physical, moral, and intellectual life.

"Educate the people" was the first admonition of Penn to the colony he had founded. "Educate the people" was Washington's richest legacy to the nation. "Educate the people" was the unceasing exhortation of Jefferson, whose last years were concerned chiefly in establishing in Virginia a system of public instruction, the fruits of which are seen in her splendid institutions of today. So too with the arts and sciences. From the earliest days, liberal provision by the state and nation has been made for their establishment and maintenance at government expense. Astronomy, geology, and climatology, not to mention their kindred sciences, have received substantial encouragement and support from the public treasury. Not so, however, with the great science of medicine and surgery. From the days of Hippocrates to the present, medical science has fought its own way, developed its own progress, and established its own systems. And especially is this true of our own department in that great science. "Like the spider spinning its web out of its own inwardness," it has developed and expanded, unaided and alone, till it stands today as one of the foremost professions of the world. The great problem of education, of whatever character, has ever been, and still is, to secure in due proportions instruction and the development of the mental faculties. It is this which constitutes the chief difficulty, both in the common education of childhood and the special education of later life.

The human mind can be trained only by facts imparted to it, and the first object of all teaching is to so impart facts as to educate the mind in scientific thought that it may be able to found a judgment on the facts presented. To ac-

cept as true all that established authority says is true, or to fill the mind with such statements by an effort of the memory, is false teaching, since by it the mind may become stored with error instead of truth. To determine that which is true or false, and to arrive at just conclusions, is of far higher value than a mere memorizing of facts, and should be the primary and ultimate object of all teaching. "And to thus teach," says Dr. Watts, "the instructors should not only be learned in the sciences which they teach, but have skill in the method of teaching, and patience in their presentation."

No intelligent man doubts for a moment that one hour's teaching by an expert is far more valuable to a pupil than two hour's instruction by a mere routine teacher, or that truths are far more effectively taught by those who have been tempered for their work by the glow that comes from a growing insight into some chosen mental field, and who know what devotion to truth for its own sake means. It is men thus trained and disciplined that are desired as teachers in our profession. Not that many of those hitherto and at present connected with our institutions of learning are not men of experience, education, and devotion; they certainly are all of these, and deserve the highest commendation and respect for what has thus far been accomplished through their efforts and skill; but who of them all is not required to divide his time, energy, and thoughts between his daily practice and his hours of teaching?—between a necessity for bread and a desire to impart knowledge?

It has been truly said that no artist, however skilful, who paints his pictures for so much apiece, or who is required to paint that he may live, can produce his best results. His must be a labor of love; he must be above financial necessity; his mind and energies must be given without pollution to the study of the true science of his art, if he is to exercise and display his greatest genius. And what is true of the artist is equally true of teachers and institutions. Any system of education which does not keep men constantly at

their best work is unbusiness-like and wasteful; and who can estimate the loss already sustained, in that Miller, Black, Williams, Andrews, Truman—not to mention scores of other equally conscientious though perhaps less-known workers—have been unable to give themselves wholly to study, investigation, and instruction?

That the agitation for higher dental education and improved facilities for acquiring it is to become widespread and permanent, I fully believe. That it will also receive opposition and discouragement is safe to predict, for there are always those who, while not openly opposed to a forward movement, nevertheless do not accord to it the encouragement and support necessary for its accomplishment.

Among the many fallacies of the day that pass unquestioned there is none more fallacious than that change is popular. The truth is, he who seeks to alter the established order of things is likely to be, for a time at least, the most unpopular man in the community. He will be hated by those who are satisfied with the old evils; he will be disliked by the timid and lazy, who dread the perils and troubles of a change; and he will receive little encouragement from those most conscious of the evils, because his remedies will not act as a charm and remove in an instant the accumulated ills of centuries. We are not always conscious of the fact that in man the love of ease is far superior to the love of change. In the serious concerns of life, change is never desired for its own sake; habit becomes second nature, and it is only by the positive pressure of evil that we are driven to any reform. An old system must ever have two advantages over a new one—it is established and it is understood. We ought not therefore to be over-anxious to encourage a change in case of doubtful improvement; but in undertaking to bring about an improved condition in our educational system we are seeking that which will confer upon our profession and humanity benefits which cannot be properly estimated.

We are living in the present, but we must think in the future, and strive to

build for those who are yet to come. The present becomes the past, and the future the present, in such rapid succession that the man who in any of the serious concerns of life does not think and live in the future, is certain sooner or later to find himself hopelessly in the past. And what greater incentive is there than this knowledge to awaken in us an irresistible desire and earnest purpose to lay broad and deep the foundation of that system which underlies all other systems—namely, the system which educates our students, and determines the character of the education which they receive?

Years undoubtedly will be needed for its complete accomplishment; but the gain of a little here and a little there, and the aggregate brought together into one complete, uniform, homogeneous whole, in which each and all are striving to encourage and assist in every honorable way, must eventually result in educational facilities for our profession which shall, in a larger measure, meet our peculiar needs.

Discussion.

Dr. CHARLES McMANUS, Hartford, Conn. The thing that strikes me most forcibly in the paper is that it is a radical study of the educational question presented in a very high-minded way. In the consideration of this subject, it is of course necessary to deal with several classes in the profession: those connected with the colleges, those connected with the boards of examiners, and perhaps a third class, which comprises what we may call the plain dentist, to which class I sometimes ask the privilege to belong, although, as Mark Twain said, I have friends in both of the other classes.

Evolution, of course, is something which looks to the future. It is certainly a fact that in the past many of the older colleges have had to depend for their strength largely on the personality of the great men connected with them; but possibly in the future, when our colleges will have become departments of the great universities, this will not obtain so generally.

As to dental examiners, I believe that there are some of them unworthy of the name. It seems necessary that we should have them under the present system; they must be there as a sort of dental policeman, but if our educational system can be placed on the high plane spoken of by Dr. Butler, there will be no necessity for the state dental examiner, and the best of them will be glad to find their occupation gone.

In closing I wish to speak of one particular phase of the paper—that in reference to the men who are dissatisfied but not disaffected; and it seems to me that therein lies the hope of dentistry or any other calling which desires to progress. The man who is dissatisfied is ambitious; he is a constructionist—a builder-up; but the man who is disaffected is what we call a pessimist—one who tears down, and that phrase is the keynote of the paper—that there are so many in the profession who are *dissatisfied* but not *disaffected*.

Dr. S. H. GUILFORD, Philadelphia. Like Dr. McManus, I listened with great pleasure to Dr. Butler's paper, and if I were to criticize it, I should say that the best part of it was the rhetoric and the delivery, and that the poorest part was the ideas it contained. When I say this, I do not mean the general ideas to which Dr. McManus referred, as I think they are commendable. Dr. Butler is reaching toward something in the future; something both great and grand, but when we consider his suggestions as to how to realize these high ideals, I regard them as utterly impractical and impracticable. It is very easy to present ideas and ideals, but we should have some knowledge as to how to bring them about. We should go into details, because without details we cannot hope to have the superstructure we are looking for.

In regard to the problem of eliminating the independent colleges—the small colleges—and establishing others in certain districts, and having them give all the dental instruction, it seems to me that the proposition is very much as though the board of trade in some city should say, "We have too many retail stores in this city. We want to eliminate the

smaller shopkeepers and have only large department stores—one here and one there, readily accessible to the people.” Now, would such a thing as that be practicable? Could we rob the small storekeeper of the privilege of conducting his business to the satisfaction of the people who trade with him? I say it cannot be done. The next question is, Would it be desirable to eliminate the small stores and have the work concentrated in the larger ones? Or, to make a similar application in matters of education, Would it be well to eliminate the small institutions of learning, and have them all concentrated in larger schools of education? I think that in order to decide this question, it would be well to consider what has been done, or what has been tried in other ways. Let us take the case of general education. The question as to whether education is best conducted in large universities, or in the smaller colleges has been a living one in this country for many years. There are two things to be considered in regard to that matter; one is that in the larger institutions there exists a sort of fraternity spirit—that spirit which counts for something. The young man comes in contact with many other young men, he rubs against them and becomes polished, and the influence is a good one. On the other hand, the man who enters the smaller college does not acquire that great spirit that pervades the universities, but he comes into closer contact with his instructors; as the classes are smaller, the teacher gets nearer to the young men, and the personal influence exerted by the teacher over them is important and valuable—far more valuable than that which comes from what we call the university spirit. Therefore, this question has two sides—one in favor of the larger university, and the other in favor of the smaller colleges—and as it has not as yet been settled for general education, I do not think it will ever be settled in our time for professional education.

Now the presumption is, as I take it, that if our educational institutions were incorporated in a few large universities, better results would be attained so far as

teaching is concerned. This plan has not been productive of such results in other professional schools. We have many professional colleges that do not have such a great number of students, but many of the students graduated by these schools become very remarkable men. For instance, in Philadelphia we have the Jefferson Medical College, which is not connected with any other institution whatever; it is not under the supervision of the state authorities, and yet from it are turned out as many eminent men as from any medical school in the country. The teachers are great teachers, and nobody questions their ability or success as teachers. When we come to the question of the fitness of the men educated by the different schools, if you look throughout the dental profession today, select its best teachers and find out where they received their education, you will find that most of them have come from the smaller colleges.

I consider Dr. Butler's ideas with regard to incorporating the independent schools in the universities as impractical. How are we going to bring about this combination? We have throughout the country many colleges—fifty or more, and how were these colleges established? They were established by a number of dental practitioners who were willing to give their time and money for the purpose of founding them and building them up so that proper education might be given to the young men entering the profession. How would you dispose of these men? Many of them have been teaching in these colleges for years, and are dependent on the salary they receive for their teaching. They have given time from their private practices to devote it to the teaching of students, and in many instances their practices have greatly suffered thereby, and in others have dwindled down to almost nothing. Now, what are you going to do with these men? You cannot care for them except in one way, and that way Dr. Butler did not suggest, namely, that we gather together in some mysterious way a large fund to reimburse these men for the sacrifices they have made.

In regard to the question of the boards of examiners, or the interchange of licenses—perhaps I can throw a little light on that subject by illustration. Quite recently I was in Canada, and I learned there what interested me greatly. They have been struggling with the problem of state boards or interchange of licenses, and they have brought about a tangible result. The Dominion of Canada is divided into nine provinces, and they have agreed that its own legislative body shall make the dental laws for each province. They have established in each province a board of examiners, which conducts the dental affairs of that province in the same way as the state boards in this country conduct the affairs in each state. They may adopt a high standard or a low one as they please. When a man wants to practice in a certain province, he must pass the examination prescribed by the board of that province, and if successful he is licensed to practice in that province and in no other. But the boards in these provinces have come together and agreed to form what is known as the Dominion Dental Council. That council is composed of two representatives from each province, being selected by the highest dental organization therein. These eighteen men constitute the Dominion Dental Council. They hold examination at certain places at certain times, and if a man who is practicing in any province wants to appear before that council, he can go there and be examined, provided he has previously obtained a certificate in one of the provinces; and if he passes the examination of this council satisfactorily, he is given a certificate which entitles him to practice in any of the provinces of Canada. There, gentlemen, is a practical result. Now that would be difficult to bring about in our own country because of so many states, and yet they tell me in Canada that in order to get this interchange among those few provinces they have been working for years with the different legislatures until they finally accomplished this result. Though this represents long and arduous work, it seems to me that it is an idea that we might appropriate with advantage, and

in that way overcome some of the difficulties mentioned by Dr. Butler.

Dr. S. L. GOLDSMITH, New York. I think we should hail Dr. Butler as being in the same class with such men as Jules Verne—as a man with a visionary imagination. I think, however, that he is nearer the realization of his ideas than Jules Verne was, because it seems to me that Dr. Butler is going to see his hopes realized during his lifetime.

In speaking of the profession as being divided into two classes—those who are dissatisfied and those who are disaffected—I think he should add one more classification, namely, that of those who are disinterested. The discussions of the men who speak on this subject must be weighed. We must consider what power is behind the throne; what is the power actuating the man, and then we may read between the lines.

The gentleman who preceded me, and whom I have known and respected for many years, has made comparisons between the dental educational problem and the workings of a board of trade. Gentlemen, are you willing to be classified with anything that is commercial? Can there be any comparison between commercialism and professionalism? There should be no competition between colleges except in matters of education. The great trouble with the colleges is the question of being able to pay the professors adequate salaries. They must make the revenues from the clinic room and the students' fees sufficient to meet the expenses of remunerating the professors; and by what right does an association of colleges assume to dictate to its members the fees they shall charge? The only question should be the question of educational standard of the different colleges. Is it in commercialism or in the maintenance of education and professional standards that the National Association of Dental Faculties has an excuse for its existence?

The question of the classes being too large in the larger institutions is simply a question of economics. It is true that if you have very large classes under the instruction of one man, the personal as-

sociation of the professors and students will be less close; but it is possible to preserve that educational feature in large classes by subdividing them into a number of sections each under the supervision of a teacher. No educational institution should be expected to be self-supporting, and in my opinion only such colleges as are fully endowed, and those under governmental care, can lead a useful existence.

Dr. J. V. CONZETT, Dubuque, Iowa. I have nothing but commendation for the paper. It may be true that Dr. Butler's ideals may not be possible of attainment, but nevertheless that is no reason for denouncing them, or for saying that an ideal should not dominate the minds of the profession. It seems to be the best ideal we could have, although it may require many years to reach it, because our system of education must be of necessity a process of evolution. It is true that great things have been accomplished by our present system of education; great and honorable men have been turned out under it by the small colleges; and yet, on the other hand, it is likewise true to a very large extent that the commercial spirit has been fostered by these small colleges. They of necessity must depend for their existence on the fees received from students, and on the receipts from their clinics. Everyone is influenced by his environments, and this is where the student acquires the commercial spirit.

In the state of Iowa we have had three schools, and every man who is not connected with the schools regrets that there should be more than one school. One of them, however, has recently gone out of existence, which I think is cause for congratulation. There should be but one school in the state, and the university school will not be what it should be until the others are eliminated. The small schools do not have the highest class of men, simply because they have to depend on the fees received from their students, and they cannot be as strict as they should be in their requirements for entrance. The small schools must have men because of the dollars and cents they mean to the school; and men have

come to me and asked the standard of preliminary requirements of such and such a school, and after being told have gone to other schools where the standard was not so high, and been accepted. There are many of these men who can do little more than read and write, practicing dentistry in our state today, who have been graduated by the commercial schools, as we call them. While it is almost impossible to eliminate these schools, I believe our efforts should be for elimination as far as possible.

Dr. Guilford has cited the case of the Jefferson Medical College of Philadelphia as a successful professional school not connected with any university. Undoubtedly there are some good schools which are not affiliated with any university, and yet these schools are hopelessly in the minority. Because of the fact that these schools must stand alone, it is almost impossible for them to stand on the highest professional basis.

With regard to the examining boards, they are a necessity, but if we are ever able to attain to the high ideal given us by the essayist, I do not believe the examining board will be a necessity.

Dr. Guilford spoke of Canada and the interchange of licenses there. I believe that is in direct line with Dr. Butler's ideal, and if we are able to work out that idea in this country it will not be necessary for us to spend so much time in attempting to obtain reciprocity between the states. If we had our education concentrated in the universities, they could readily agree upon a plan by which some such board as that spoken of by Dr. Guilford could come into existence, and then all would be able to practice in any community whatsoever.

Dr. W. R. CLACK, Clear Lake, Iowa. Dr. Butler has said some very disagreeable truths in a very pleasant manner. Not all of us are able to say these things in the nice way he has said them. Even Dr. Guilford has subjected himself to criticism when he gave the illustration he did. I do not believe that he really intended to put the dental profession of this nation on a par with the keeper of the small stores. My father was a minis-

ter, and he used to say that when God called a man to preach, He at the same time called a congregation to hear him. I believe when the Lord calls a school into existence, He is also going to call students to support that school, but a great many of these schools have not been called by the Lord, they have been called by men, and by men who have only a commercial interest in view. I know whereof I am talking, in one particular instance at least. A university in the northern part of Iowa thought they should have a dental department in order to give the university the proper standing before the world. To that end they called a meeting of the medical men of the profession in that district, and while I am not a physician, I was invited to attend the meeting, and at that meeting I heard things unwittingly laid on the shoulders of the dental profession that made my face burn with righteous indignation. They said the university needed money to succeed, and they believed the greatest money-maker they could get would be a dental department. They said, "The dental clinic always is a money-maker, and we can make that money carry along the other departments of the university." There was a man present who had been tendered the deanship of that proposed dental department, and he rose and said, "Gentlemen, a mistaken idea of the ethics of dentistry obtains among you here tonight. I was asked here under the supposition that you wished to organize a dental school upon a high plane, and my only answer to you is this: that if you wish to organize a dental school which shall be better and higher than any dental school in Iowa, I am with you heart and soul; but if you wish to merely organize another dental school, I am not with you."

I believe that course taken by the profession at large would eliminate many of these schools that have been called by man. There are so many of these smaller schools, that they are tempted by lack of funds to take any man who applies for matriculation. The profession of any state can have a dental school that is entirely above financial considerations,

if we will all put our shoulders to the wheel and work—a school the possession of a diploma from which will be "letters patent" on its face that the man has not merely *completed the course of study*, but that he is *qualified to practice dentistry*. And in order to do this these institutions will have to have men able and competent to *show* these students what they are trying to teach them. The practice of dentistry is very hard indeed to learn from text-books. The schools must have men that can show the students what they mean, and they must have men of the highest order, so that these students may be shown the highest ideals of dentistry.

Dr. Butler's ideas were spoken of by Dr. Conzett as being visionary. Gentlemen, you must have visions. It is not within the power of every man to see these things clearly, and we must set our target high or we will never shoot high.

Dr. TRUMAN W. BROPHY, Chicago, Ill. I have listened with a great deal of interest and pleasure to the paper presented by Dr. Butler, and in it I find very much material for careful consideration by men engaged in dental educational work. Certain passages in the paper I think were somewhat theoretical, and cannot be well put into practice, especially under the present conditions. What Dr. Butler needs to master in the carrying out of his views on this subject is that which some men have been pleased to call commercialism. I have found that men who discuss the subject of dental education and make reference to commercialism—if I understand what the word means—are men who have never been in the harness and learned what it is to struggle for the procuring of funds to equip an institution, to supply the necessary materials for carrying on the work and for the paying of demonstrators and teachers who must give up their time for teaching. Commercialism so looked upon and discussed should not be brought into consideration in this connection. What Dr. Butler requires would be millions of money, with which to endow these institutions so that they would never feel the need of funds for carrying on their college work as it should be done. And tell

me, gentlemen, if you can, where there is a dental institution in this world that has an endowment of a dollar? Name a state in this Union which appropriates a fund for the carrying on of dental work? And failing, as you must, to answer my question in the affirmative, and realizing that you must have money for the carrying on of dental education, then you must consider the source from which this money comes. There is only one source, and that is the fees paid by the students for their education. Can anyone name an institution that has an endowment or receives an appropriation from the state?

A MEMBER. The University of Pennsylvania Dental Department.

Dr. BROPHY. The University of Pennsylvania Dental Department has not a dollar of endowment. I am willing to submit this question to the trustees of the university for an answer, and that board will say that there is not a dollar of endowment for the dental school. This information was given to me direct from Dr. Kirk, the dean, and there are many here who can verify my statement. Two years ago—before preparing a paper on the subject—I wrote to the dean of every dental college in the United States, and asked this question, "Have you an endowment for carrying on college work?" And the question was invariably answered, "No." If there is anyone here who will rise and say that there are schools that have endowments, then I stand corrected.

Dr. GOLDSMITH. Is an endowment only possible in dollars and cents? Is not land considered as an endowment?

Dr. BROPHY. Do you mean to say that the Dental Department of the University has land?

Dr. GOLDSMITH. I mean to say that the state of Pennsylvania has given large tracts of land to the university, and that in return the latter has scholarships which it allows to high-school graduates of the city of Philadelphia; and I happen to be one of them.

Dr. BROPHY. Do you mean to say that the University of Pennsylvania is a department of the state?

Dr. GOLDSMITH. I mean to say that it has the indorsement of the state.

Dr. GUILFORD. You mean the city of Philadelphia.

Dr. BROPHY. The young man is misinformed, and I will try and set him right. I want to say that the University of Pennsylvania is not a department of the state—it is not a state institution. I will go farther, and state that it is not a state university, and I challenge anyone to refute the statement.

Dr. C. M. WORK, Ottumwa, Iowa. The University of Iowa is one of those institutions which Dr. Brophy says does not exist. It is governed by a board of regents appointed by the governor, being recommended for appointment by election from each of the eleven congressional districts. The fees which that university receives from clinics and from students is turned into the state treasury.

Dr. BROPHY. There are four state universities that have dental departments—Iowa, Michigan, Minnesota, and California.

With regard to the question of a national board or a commission, I believe that such a board or commission is desirable in this country. The only drawback is that it would interfere with the legislation of the different states. We are like a number of different governments rather than like one government. A gentleman in another country asks what the qualifications for practice are in this country; and what are you going to say? We know that when a man qualifies in one state, and goes into another and attempts to practice, he is likely to be arrested as a violator of the law of that state; and yet if he has a qualification entitling him to practice in one state he should be allowed to practice in any state. He cannot do it, however, as the laws of the different states forbid. If my friend Dr. Butler will put himself to work on this question, and get that settled, so that we will be like one nation instead of many; so that a man who qualifies to practice in New York may go to Michigan or Pennsylvania or any other state and practice, then he will have accomplished a great work. As it is, we

are the topic of adverse criticism throughout the world, because of the fact that we have no national qualification. I would like to see this rectified, and I will join in a movement for creating a national commission, made up of men who have ability and standing in the profession, before whom a man may go for qualifications that will stand anywhere and be a guarantee of his ability. I feel that this subject, discussed as it has been and presented in such a manner as the essayist has presented it, will result in great good. While none of us may live long enough to see the provisions of the paper carried out, we may live to see steps in advance that will result in benefit to the profession in general.

Before I sit down, I want to say that the dental institutions of this country stand today on an equality with any of the professional schools that we have. I am proud of the fact, Mr. President, that the dental colleges of the United States in the last twenty-two years have created a condition of things far beyond that which the most earnest workers in dental education deemed possible. We have advanced the standard of dental education to where it is at the present time. We have extended the course of instruction from one course of four months to a course which now means something definite. And in this connection, I want to say that the standard of dental education as adopted by the National Association of Dental Faculties is better than any ever proposed before in the United States. We have a standard that means something. We have a standard in days and hours of time. We have a standard, not in an uncertain term of years which means nothing definite; we have a course of instruction extending over thirty weeks of six days each in each year, and continuing for three years, which gives as much as a four years' course of seven months, less about forty days. Some of the schools have adopted the thirty-two weeks' course, and if you will consider that, you will see that thirty-two weeks of six days each week, exclusive of holidays, means the same as the four years' course of seven months.

Now, when we consider that, we cannot say that the colleges of this country are encouraging a retrograde movement. If you had seen at our meeting the number of colleges desiring to advance the standard, you would have been convinced that we are working to hold the institutions together, to increase their usefulness, and lift the standard so that America will be in the future as it has always been in the past—among the first in the world in matters pertaining to the advancement of the dental profession.

Dr. C. W. RODGERS, Boston, Mass. I rise to discuss that portion of the essayist's paper with reference to the abolition of the state boards.

I desire to state that I come from a section of this country where the condition that the essayist wishes for actually exists. I have reference to university connections. In the New England States we have but two dental schools, and they are both connected with universities. I believe that this fact in itself has not helped to place dentistry in New England on a higher plane than have the various non-university schools of Philadelphia. Also this university connection has not carried with it any call for the elimination of the state boards.

The essayist seems to think that if we could have this national commission appointed we would not require the state boards. Now, the fact is that the state boards have been of the greatest aid to the two schools in New England. They have constantly kept them aiming higher. Another fact: If you go before the state legislatures and ask for the elimination of the state examining boards, and ask their approval of a national commission such as the essayist desires, you will run across a hard proposition. You would aim at destructive legislation and interference with states' rights, of the maintenance of which the state legislatures are individually very jealous.

The proposed legislation would be destructive, because its intent is contrary to the genius of our institutions, and if enacted would tend to aid in undermining our whole democratic system of government. Why, gentlemen, it is

possible at the present time for a boy to ascend to the presidency of the United States without having seen the inside of a primary school, and you would ask legal aid to have conditions such that the boy with the ability to rise to the presidency could not rise to the practice of dentistry unless he be a graduate of a dental school. Our New England legislatures, when they gave authority to the state boards to examine applicants, did not say to them that they should examine graduates only, and it is none of the business of the board where a man gets his education, so long as he has it. That is the point we should not forget. The same idea is carried out in the catalogs of the various dental schools. They require a high-school certificate or its equivalent, and the word "equivalent" stands for an important principle.

I consider that the suggestion of a national commission supervising the system of dental education is all wrong.

Dr. BUTLER (closing the discussion). In closing this discussion, there is very little to be said in addition to what has already been presented in the paper itself.

I am not at all surprised or disappointed that those who have discussed it have failed to grasp its conception, or to rise to the level of its thought. I scarcely expected them to do so, as it looks rather to the future than to the present, and is along lines which have not heretofore engaged the attention of the profession, and on which our educators have not been thinking. Hence it was hardly to be thought that a change so radical, no matter how commendable, would at once meet with favor.

We fail to realize, also, that all our advancement has been attained only after long, earnest, and sometimes contentious effort, and that it is always necessary for someone, even at the risk of unpopularity, to lead in any forward movement.

That reforms in our educational system are needed to meet the requirements of the profession all admit; that they are to come I am sure we all believe; but how and in what way is for the wisdom of the profession to determine. Just at pre-

sent the greatest obstacle in the way of reform is the fear among our college men that any change, however simple, which will disturb the present condition of things will be harmful, and therefore is to be avoided. These men seem not to appreciate that our whole educational development has been, and must continue to be, a matter of slow growth. But as I said in the paper, we *must* grow, and to this end there must be constant unremitting and intelligent effort; and while the wisest advancement may not be along the lines I have indicated, yet it must be along some lines that will lead to a deeper, broader, and more comprehensive system.

To me it means much that within the past six years England has organized, equipped, and put into active operation not less than five universities for general and special education. And not the least interesting thing about these colleges is the fact that they are organized along the lines of our American universities, and that the dominant department in each partakes of the character of the principal industry of the town in which it is situated. For instance: Birmingham—Metallurgy and mining. Liverpool—Tropical medicine, marine biology, fisheries, electrotechnics and physical chemistry. Manchester—Chemistry and physics as they relate to cotton industries, and with a department in dentistry. Leeds—Cloth-weaving with a department in textile dyeing, coloring, etc. Sheffield—Ironmongery, cutlery, and mining.

Of course all this has no bearing upon the question of dental education, except as showing the general tendency along special educational lines in the industrial world. But are we to expect less in the professional world? It seems to me, not. On the contrary, should not professional advancement and the special education attending it lead everything else?

There is just one thing, I am pleading for today, namely, a wider interest in the profession itself in behalf of dental education.

Our college men are interested now; but we need more than this. With the

whole profession actively and earnestly interested, there can be no question about the future. That the suggestions of the paper are entirely practicable, I have no doubt; that they are the best that could be adopted at this time, is for our wisest

men to determine; but in any case it is for this association to lead the profession out into wider and more adequate facilities for acquiring the education our specialty demands.

(To be continued.)

NEW YORK ODONTOLOGICAL SOCIETY.

Monthly Meeting, October 1906.

A REGULAR meeting of the New York Odontological Society was held on Tuesday evening, October 16, 1906, at the Academy of Medicine, No. 17 West Forty-third street, New York city. The president, Dr. Van Woert, occupied the chair, and called the meeting to order.

The Secretary read the minutes of the last regular meeting (that of April), which were approved.

The Secretary read the resignation of Dr. I. Franklin Wardwell. On motion of Dr. W. W. Walker, the same was received with regret.

Dr. WALKER. I know the members will all be sorry to learn that our friend, Dr. S. G. Perry, has been very ill. About ten days ago he was lying at the point of death, and had it not been for the efforts of his old physician, in consultation with three others, I doubt whether he would have pulled through the crisis. However, I received a telephone message today from Mrs. Perry, saying he was a little better and able to walk around. It would have been a very sad thing to have lost that dear, sweet man, who has been so kind and good to all of us, and I am sure you will be glad to know that he is getting better.

Dr. Dailey says we might send a telegram to him, saying we are sorry to hear of his illness, and glad that he is on the road to recovery. I would make a motion to that effect.

The motion was carried and the secretary was requested to send such a telegram.

Dr. WALKER. The other incident I would like to relate is that Dr. A. L. Northrop, our old friend and associate, has retired from practice. He ought to thank God that he can do so, and that he does not have to keep on looking after buccal cavities, nerve-canals, etc. He will spend the balance of his days in peace on his farm in Ridgefield. I would move that a committee of three be appointed to make arrangements for preparing an honorary membership certificate, and to have the same presented to him in due time.

The motion was carried, and the President appointed Dr. Walker, Dr. Dailey, and Dr. Sanger as such committee.

Dr. F. B. KEPPY. I would like to move that a committee of three from Brooklyn be appointed to draft suitable resolutions for making Dr. Jarvie an honorary member of this society. He has also retired from practice.

The motion was carried, and the President appointed Drs. Keppy, Schmidt, and Quinlan on such committee.

The paper of the evening, entitled "Operative Dentistry," was then read by Dr. NELSON T. SHIELDS, as follows:

OPERATIVE DENTISTRY.

From the above title it will be seen that I purpose to describe in a brief paper the surgical care and treatment of teeth from childhood to old age.

Surgery is precise, and we can accurately calculate the result of the oper-

ation, be it large or small. In all operations every effort should be made to preserve the structural features of the teeth.

Should deciduous teeth become affected by caries, our first thought should be the preservation of the dental pulp, remembering the size of deciduous pulps in proportion to the size of the teeth. These cavities should be prepared without mutilation, and filled with the material that is most compatible with tooth-structure, under no condition using the mallet. To save the deciduous pulp by most careful manipulation is not only the best treatment for the tooth, but it enables the root to be physiologically absorbed as its permanent successor approaches the erupting period.

At the time the deciduous teeth become a little tender under the stress of hard mastication, the largest permanent molars erupt—at about the sixth year. It behooves us particularly at this time to advise thorough prophylaxis, in order to enable the saliva to come in better contact with these teeth, thus neutralizing the acids and preventing decay; and the same care should be advised regarding deciduous teeth.

Should decay or disintegration commence on the anterior approximal surface of a first molar before the eruption of the second bicuspid has begun, we must remember that irritation has already commenced in the molar pulp by transmission through the dentinal fibrillæ, odontoblasts having formed a calcified layer within the pulp-chamber nearest the decayed spot. The reduction of irritation to the dental pulp should be our first consideration, and the prevention of further irritation through further decay the second. In the preservation of normal conditions I most strongly advise the removal of the decay only—but to the full extent of the affected enamel—extending the cavity only deep enough to allow for the introduction and stability of a perfect filling. Now we have a filling on the anterior approximal surface of a first molar before the patient is ten years old, with tooth-structure clear and healthy all around this filling.

Through the agency of the saliva, and through prophylaxis, we may never have caries appear on this surface again, but should decay appear five or six years afterward, the walls of the tooth will have become so much thicker and so much more dense by the natural recession of the pulp that we can at this time prepare the cavity, and if necessary extend it through the occlusal surface, removing all decay from the fissures and not allowing the filling to end in a fissure. But not even at this time should the cavity be extended by cutting solid tooth-structure, and unnecessarily irritating the dental pulp, which will contain calcified formations in the pulp-chamber beneath the grinding surface and along the anterior approximal wall.

After the eruption of the second molar, at about the twelfth year, the first molar may decay on the posterior approximal surface, and it may be necessary to extend the cavity to the occlusal surface, which should be done without too much cutting, especially in the direction of the cusps, where the irritation to the pulp would be greatest. This filling contoured to the anatomical form of the tooth, and the material thoroughly adapted to the walls will surely, under ordinarily healthy conditions, preserve this tooth until the patient's thirtieth year or longer. Should decay appear at this time, we know that every care had been exercised in the prevention of irritation to the pulp, and that the calcifications have formed at a point farthest away from the foramina or entrances leading from the pulp-chamber to the root-canals, and we can without fear of subsequent irritation extend the cavity beyond the contact point of the approximating tooth, and introduce the filling with the expectation of a permanent result. In the preparation of this cavity for permanent filling it will not be necessary to excavate below the cervical margin, neither will it be necessary to cut a great flat slot in the grinding surface for strengthening the filling, as a very much smaller occlusal excavation, with a slight stay or undercut in the direction of each cusp, will be just as strong and will

obviate the necessity of mutilating the tooth.

For permanent work it is not necessary to bevel the buccal, lingual, and palatal walls, as a straight wall free from approximal contact is more artistic in appearance. Such a technique results in a stronger tooth and in less irritation being inflicted on the pulp, but the enamel being thickest at the grinding surface can be beveled beyond the contact point and contoured at this time with perfect safety. The enamel could have been beveled in the previous operation, if additional anchorage in the dentin were not required.

Unfortunately, patients come to us in all conditions, and the selection of our filling material should be made with the view of saving first the pulp, and then the tooth. Combination fillings and combination of mallets should be used when it is best. In cases of nearly exposed pulps, the cavity can be lined with cement, and a crystal gold embedded or pressed into the cement, to be subsequently used as anchorage and finished with foil, first using the automatic mallet, and finishing with the electric mallet. Shallow cavities may be filled in the same way, but where strength is required the foil form of gold should always be used.

It is a mistake to have a stereotyped form of cavity in mind, and to form all cavities posterior to the canines after that model, regardless of conditions. I have in mind a case of very irregular teeth where the approximating surfaces are in close contact, practically throughout the entire surface. This patient, a Mrs. S., is thirty-seven years of age, and the cavities in her teeth were filled when she was about fifteen years of age. Although the cavities were very small and the tooth-structure touched the approximal surface of the approximating tooth all around the filling, there is today no sign of further decay. The same statement can be made regarding her upper incisors. These cavities were filled with non-cohesive gold, cohesive gold being wedged or malleted into two folds of the non-cohesive gold, and although the teeth are very irregular, their natural artistic appearance has been preserved.

Non-cohesive gold has a most important place in commencing a filling at the cervical portion of large cavities, and in producing perfect contact in all cavities with good walls. In difficult posterior cavities in third molars involving the whole cervical and posterior lingual or posterior buccal cusps and grinding surface, a gold inlay can be used to great advantage, but the general use of either the gold inlay—and more especially of the porcelain inlay—should be avoided. Crystal gold should never be allowed to come in contact with dentin, on account of its extreme incompatibility.

Ascher's enamel has so far given great satisfaction in restoring suitable cavities in canines and incisors. Last, but not least, we occasionally find amalgam in combination with cement advisable in bad posterior cavities where the expense of the operation is taken into consideration.

In the preceding remarks the maintenance of the normal condition of the pulp has been discussed but now we shall consider the subject from a different aspect.

Had the anterior approximal cavity of the first molar been filled before the eruption of the second bicuspid had occurred, by an operator advocating the "extension for prevention" principle, the whole anterior approximal surface would have been removed below the cervical margin, and in all likelihood he would have extended over most of the grinding surface, with a large slot cut into the grinding surface for strength; and without question the operation would be very much more permanent. It must be remembered, however, that the cervical margin at that time was not the cervical margin of ten or even five years later, and large calcified bodies would rapidly form at a point very much nearer the foramina of the anterior root-canals, and from this irritation pulp-stones would be liable to form throughout the entire pulp, causing congestion of that organ at the age of twenty-five or thirty—or at any period before—and necessitating the extirpation of the pulp. The same result would be likely to follow had the cavity

been filled at the age of twelve or fifteen years.

Cervico-labial and cervico-buccal cavities in the anterior teeth, whether caused by caries or acid erosion, may be filled with either porcelain or Ascher's enamel with good results. These cavities are very irritating to the pulps of all teeth, for the reason that the blood has to circulate around the calcification, and congestion is more liable to follow a few years later. I will state here that I have seen many cases of uric acid diathesis where the crowns of the teeth had been reduced one-third of their original diameter from the labial and buccal surfaces without the roots being exposed, the teeth remaining absolutely tight, for the reason that the calcified formations were confined to the crowns.

Even with the best of care we are liable to have congestion in the dental pulp, and when it is recognized, through such symptoms as sore teeth, pain in the arms, nervousness, headache, pain in taking anything hot or cold, recession of the gum, ulceration, etc., then carefully ascertain the affected tooth or teeth, open into the pulp without causing pain, employing sharp burs and correct manipulation, and extirpate under cocain this wonderful tooth-builder, which has now become a tooth-destroyer.

The fact that the vital nature of the teeth demands careful steps to avoid and to allay all irritation is offered as my reason for this positive stand against the indiscriminate application of the principle of "extension for prevention."

Discussion.

Dr. JOHN A. SCHMIDT. I had the pleasure of reading a copy of Dr. Shields' paper. It is opportune in this age of extension for prevention. The paper is an excellent one, and shows the essayist to be not only conservative, but humane. It is well to consider the points he has raised, and to follow the sequence of irritation to the dentinal fibrillæ, viz, secondary dentin, pulp-nodules, neuroses, and death of the pulp, with its sequelæ.

Regarding the care and treatment of

the teeth of young children, it is exceedingly difficult to have them carry out the instructions regarding prophylaxis. This I have found to be the case with my own children, and though time and care have been given to their teeth in this matter, the results are not much better than with my other little patients. As Dr. Shields has said, to cause the roots of the deciduous teeth to be physiologically absorbed we must preserve the life of their pulps.

What does he consider a compatible filling material in deep-seated cavities of the deciduous teeth? Take for example two compound cavities extending to the gingiva in the approximal surfaces of the first and second molars.

The pulp of the first molar, at the age mentioned by the speaker, is highly vascular. Avoidance of irritation of the fibrillæ, and also of strain on the nervous system of the little patient—the latter a very important factor—must be taken into consideration. Would Dr. Shields fill such a cavity with gold? I believe—for the reason that prophylaxis is not carried out as fully as is desirable—that these cases usually require another filling in four or five years.

I cannot agree with the essayist in placing a gold inlay in a third molar, the cavity involving the whole cervical, postero-lingual, or postero-buccal and grinding surfaces. This I deem an unfavorable place for an inlay of any material, and it is the selection of such cases that gives a black-eye to inlay work.

I have had a large experience with inlay work, and my failures have been where I have attempted it in cavities where I would not attempt to use gold. Inlay work is all right, used in proper places and under proper conditions; my own failures have been in just such instances of poor judgment. The use of the rubber dam is as necessary for success in this work as in gold work.

That third molar can best be saved by the use of a combination cement and amalgam filling, working the amalgam into the soft cement, and giving special care to the edges. The cement affords adhesion, avoids the use of deep undercuts, and lessens the susceptibility to

thermal changes; but be sure to place a thin gutta-percha layer over the deep-seated portion, as the oxyphosphate is liable to be irritating, although the oxyphosphates of today are far superior to those we formerly were compelled to use, and are claimed to be free from the slightest trace of arsenic. I put in many of these fillings, not to avoid expense, but because I know that it is the material best adapted to the case.

Why is crystal gold more incompatible with dentin than are other forms of gold? Is it not entirely free from the acids used in the process of electrolysis?

The method followed by many of our best operators, of using a creamy oxyphosphate and working into it the moss fiber gold, finishing with gold foil, has a tendency to eliminate to a large degree the irritation produced by extension for prevention, deep undercuts, and thermal changes.

Regarding Ascher's cement, I would like to hear from others as to its value. I have used it but a few months. It is easy to insert, of low conductivity, and can be mixed to match almost any tooth; however, I have used it sparingly, thinking that possibly it may be an improved Archite cement.

Another cause of secondary deposits and their sequelæ is the proper preparation of a living tooth for a gold or a porcelain jacket crown. This is possible even when the crown is set with gutta-percha; as for example in the case of bell-shaped crowns. We frequently cut close to a horn of the pulp. Regarding the life of pulps after the beginning of secondary deposits, I will quote Dr. Black: "Life may extend from a year or two to half a lifetime or more, but a very large proportion of these pulps are lost within ten years. Some of these cases will result in abscess, but very many pass on for years in a state of perfect tranquillity, giving no indication of death of the organ."

Dr. M. L. RHEIN. It is rather a difficult paper to discuss, as the title covers almost everything. We all know the results and quality of Dr. Shields' work. There is a vast difference between theory and practice in operative dentistry. For

my part, it is an impossibility to lay down to any student or practitioner a method of preparing or filling any theoretical line of cavities, because in my own limited experience I have never seen two cases that called for the insertion of exactly the same kind of filling. I say that with about as much emphasis as anything I could on this subject, and if it be true, it is the strongest argument that can be brought against the acceptance of the main portion of what the essayist has said tonight. Dr. Shields has not presented this matter to us for the sake of being complimented on what he has done, but no doubt desires to have what he has said criticized; and what little I have to say will tend in that direction.

There would be a great many more works on operative dentistry before the profession if it were not that we must study each individual cavity that presents itself, in order to decide what is best for each case, taking into consideration not only the condition of the mouth, but the age and temperament of the patient, and every small contiguous circumstance that relates to the operation.

Of course we do have a general variety of cases that resemble each other to some degree, and in regard to those cases the essayist has promulgated a form of pathology this evening that is astonishingly new to me. The study of diseases of the pulp—and, when I say that, I mean any variation of the pulp from its physiological and normal character—is in its infancy. It is one mystery that dentistry has not solved up to the present, and it is to my mind a most interesting subject for scientific investigation. In a few words, the essayist claims to have solved this question: I doubt it very seriously. He said dogmatically that pulp-calcification starts in certain positions in the pulp when certain things are done, and that it does not start in this position when other things are done. My experience is at variance with that. I might say without boasting that I have given a great many years of careful study, although not as much as I would have liked in this busy bread-and-butter existence

we must lead, to classifying the different forms of divergence of the pulp from the normal.

Dr. Vida A. Latham of Chicago, who I believe has given more attention to this subject than all the rest of the dental scientists of the world, has told me how little—notwithstanding the amount of time she has spent at such work—she has really accomplished, and what a vast amount of work there is still to be done. It is idle for anyone to set up a dogmatic statement, based purely on clinical deductions, as to the pathological conditions of an organ in which the variations are so microscopic as is the case in the pulp. In those first and second molars which the essayist has mentioned, where attempts had been made to just help the teeth along, inserting fillings that would save them for a certain time, without attempting to put in what may be termed permanent fillings—whether they were cement fillings, or amalgam, or gold—the sum of my observations is that following such procedure I have found the most pulp-disease and the greatest amount of calcic formation that ended in pulp-destruction; and *vice versa*, in those cases where it was feasible to fill those teeth permanently with gold I have found the least amount of subsequent pulp-inflammation.

Here we are—two operators giving our own entirely different dogmatic opinions and observations. I have no doubt that Dr. Shields' observations are fully as honest as my own, and I do not say this to set up my own observations as having any great amount of value, but to support the assertion that this is a subject on which we are unable to speak with any degree of authority. I refer to the question of the etiology of diseases of the pulp. Let us stop for a moment, and think what happens when caries attacks a tooth. As soon as the smallest amount of that tooth-substance is involved, irritation has started, and we know that inflammation must result; and we also know from microscopical examinations of thousands of pulps that no such tooth will contain a healthy pulp. That we *can* say dogmatically, because in

the thousands of teeth in which the pulps have been examined, that one matter has been settled; but to what does the disease of the pulp lead, and how can such a pulp be retained, even if it be at variance with the normal type, so that it should not be lost and so that extensive calcic interference should not take place? These are mysteries to us at the present time.

There is no doubt that exaggerated extension of cavities in young people with certain temperaments and in certain conditions of health is not only uncalled for, but would be brutal if attempted. On the other hand, where caries presents itself in the mesio-approximal surface of a first molar before the second bicuspid has erupted, and the patient is a sturdy child with a temperament such as many children have, looking upon operative dentistry as a pastime if it be properly presented to them—and I have seen hundreds of such children—the extension of such cavities on the plan outlined by Professor Black—and followed for so many years by Dr. Marshall H. Webb and some of the operators who antedated him—if properly completed should result in the introduction of a filling that will save such a tooth permanently, with less discomfort to the future of the patient than any of the means advocated by the essayist. No one here will attempt to deny that the contouring of the approximal surface is an easy matter at this time. It can be done in less time and with more ease than later in life, when the bicuspid is in position. This is one of the strong arguments for a permanent operation at such an age. The argument as to its greater detrimental effect upon the pulp I positively deny, because the essayist has absolutely nothing but his own experience to substantiate such an argument, and it is entirely contrary to the experience of many good operators.

In reference to the other point made, as to further extension of pulp-disease, so that ultimately the pulp is lost, which will and does often happen, I might as well tell you my theory; it is a simple one. If the child grows to manhood or womanhood strong and robust, there will

be no trouble with the pulp; but if beset with ills and woes—has grippe, pneumonia, or scarlet fever, and all that sort of trouble, the diseased pulp will be more diseased and in a worse condition. It is the weak point in such a patient's mouth, and will be the seat of trouble that would not affect it if the child went on to maturity as a robust, healthy person. If such a pulp becomes diseased to such an extent as to necessitate it, its removal is more easily and more correctly done through the occlusal portion of the tooth, without disturbing the original contour of the approximal restoration. It is then possible to thoroughly and aseptically cleanse and fill such root-canals, thus placing the tooth in a condition where it will not give trouble later in life. It is certainly easier than this constant re-filling of teeth.

As far as I can make out, the main tendency of the paper was a plea against what I have just advocated—a plea against the permanent filling of such teeth at a youthful age. In what I have said I want it distinctly understood that there are many cases where the essayist is right; but his method is excusable only when the temperament of the patient and the surrounding conditions are abnormal. Where those conditions do not exist, I do not consider that it is good dentistry as regarded in its present advanced stage.

One last point I will touch on is where the essayist speaks of starting a filling with soft gold, using foil first with the automatic mallet and then finishing with the electric mallet. When he said he would finish with the electro-magnetic mallet, I supposed it was because he believes he would get in these posterior teeth a stronger and better filling; but I cannot understand why he should want to use an instrument such as the automatic mallet at the outset, when the electric mallet, used as soon as a mallet should be used, would not only do the work more rapidly, but condense the gold more thoroughly. He may have some reason for doing so, but to my mind the blow of the automatic mallet in the interior of the tooth is about as bad a thing

as I know for causing shock to a patient. The greatest advantage of the electro-magnetic mallet is that with the enormous rapidity of its blows—from 3300 to 3500 a minute—shock is reduced to a minimum, and condensation of the gold carried to a maximum degree.

Dr. OTTOLENGUI. I believe that if we had many papers like the one of tonight, we would suddenly hear of a new school in operative dentistry, with a system of its own, and Dr. Shields would belong to the old school, because the gist of his paper, as I get it, is an antagonism of the new system. It is true, as Dr. Rhein said, that every cavity is a law unto itself; but all cavities are amenable to a definite system of work. Teeth can be filled, as was said long before I was born, not only with method but with judgment, and one must use judgment whether one has a system or not. It is a mistake to oppose a system of filling teeth merely because a few extremists have possibly carried it too far. It would have been much better to have upheld the system, eliminated its faults, and brought out the good that is in it.

In one of the western societies last year, ten men from the West gave a very interesting clinic. They placed their chairs in a row, and started to operate on their patients simultaneously. Each prepared a cavity. As soon as his cavity was prepared, he laid aside his instruments, and empty-handed, walked one chair up—a sort of progressive filling party. He then operated on the next patient, and without altering the shape of the cavity, filled it. Having done this, he left that chair and walked to the next, and finished and polished the work which his predecessors had done; and when the work was all finished, the ten were pronounced perfect fillings.

Now, gentlemen, you cannot object to a system which enables men to fill teeth in that way. I enter my protest against that portion of the paper in which it is said that we cannot have a definite method of filling teeth. It used to be said that we could not have a definite method of filling root-canals, but we have.

I want to say a word about children's

teeth being filled with gold. It seems to me that it is much better to fill a tooth once than ten times. There is no more danger—or very little more—in filling a deep cavity in the young tooth than in filling a cavity the same distance from the pulp later. The depth of the cavity should be measured from the bottom to the pulp, and whatever one would do to protect the pulp which is nearly approached in a young tooth, is just as essential to carry out in an adult tooth. The pathology is just the same, and the danger of mistakes is just as great. There is no reason why a young tooth should not be as finally filled as a tooth in an adult mouth. The only point is, that it is generally considered that young people will not submit to the operation as the older ones will, but that is a matter of personal equation—a matter of the ability of the operator to manage his patients. In many practices men can manage adults better; I have rather made a specialty of children, and long ago, when people asked me how I succeeded with the young, I would say, "I treat children like grown people." The children end of my practice I find is growing. And when it comes to saying how I manage adults, I must say that I treat grown people as I do children—and that is the sum and substance of the whole thing. Teeth are teeth, and each cavity must be considered in connection with the temperament of the child and the possibility of making a perfect filling, regardless of the youth or age of the patient. If a perfect filling can be put in the tooth, put it in when the patient first comes to you. Take one fee for it instead of many, and you will earn not only your money, but the gratitude of the patient.

I never have tinkered with teeth in my practice of a quarter of a century, and I have not found those dead pulps with which you are all threatened. I do believe that we look too closely to the tooth, forgetting that it is part of the body and subject to the same diseases; and very often, when pulpitis ensues and a dead pulp is found, a man is blamed for having inserted a gold filling too close to the pulp, when the pulp really died from

constitutional causes, from infection, or from some other source than the proximity of the filling.

Dr. JOHN I. HART. There seems to have been a misconception of what the essayist said. If Dr. Rhein understood the essayist correctly, then I must have misunderstood him, and I am going to state the proposition as it seemed to me. My understanding of what the essayist said about the filling of the mesial surface of a first molar was that he would place in that cavity, after having prepared it, a perfect gold filling; but he would not extend it "for prevention."

Dr. Rhein stated that it was his understanding that the essayist might put in that cavity amalgam or one of the oxyphosphates, and that he (Dr. Rhein) would extend the cavity according to the Black theory. If the essayist's remarks were as Dr. Rhein quoted them, then my leaning would be toward Dr. Rhein's practice; but if my understanding of the essayist is correct, then my leaning in practice and teaching would be toward the theory advanced by our essayist. In spite of what the last speaker has said, that pulp-irritation may be started even though we do not approach the pulp closely, I think he will concede that for the proper anchorage of a filling, where the cavity has been extended for prevention, we must approach the pulp more closely than we would for the simpler form of filling, and that the pulp is much larger in a first molar, at say eleven years, than we would expect to find it at twenty-five years; consequently I do not think we are justified in extending the particular cavities we are speaking of so as to include the whole mesial surface and a portion of the morsal surface.

Dr. SHIELDS. I heartily thank you for the earnestness of this discussion, and I am very glad that the subject interested you to such an extent.

I consider, Dr. Schmidt, that gutta-percha is a very compatible filling for deciduous teeth wherever we can use it. In an anterior approximal cavity in a first molar before the eruption of the second bicuspid, I certainly should use gold, filling the greater portion of the

cavity with non-cohesive gold in folds, and wedging the cohesive gold into the latter, making an absolutely tight filling that can be contoured correctly and which when finished will cause nothing but beautiful yellow reflections that will never turn dark.

In regard to crystal gold, the reason it is so very incompatible is simply because the gold is formed of crystals matted together, and when made cohesive these sharp crystals actually penetrate into the dentinal fibers, and are extremely irritating. I have been fortunate enough to remove many, and have found this to be the case. Whenever the necessity arises for using the crystal gold, it is easy to just touch the bottom of the cavity with a little cement, thus making it impossible for the crystal gold to come in contact with the tissues.

Dr. Black has been quoted, and I am only too glad to use Dr. Black's quotation in my own answer. I learned a great deal from his lantern slides, and they verify my own clinical experience. I also learned a great deal from Dr. Kirk's slides, and will tell you how I have applied the information thus gained. Take teeth without any cavities at all—the lower incisors are the ones to which I have particular reference. After the age of twenty-five, at any time when the little line of dentin becomes exposed the patient has not the slightest cognizance of any irritation. From Dr. Kirk's and from Dr. Black's slides you will see right over the pulp that calcified mass. You can verify other statements made in this paper from the able demonstrations of Dr. Kirk and Dr. Black.

Dr. OTTOLENGUI. I think if I remember that paper of Dr. Black's, that he made the following statement: he showed pictures on the screen of what you call calcified masses, but said that they were shadows; that they did not appear in the specimens, but only in the photographs, so I am not sure that they are calcified masses. Dr. Black has not decided what they are.

Dr. SHIELDS. They are inflamed dentinal fibrillæ—this is confirmed by similar slides exhibited by Dr. Kirk. In nei-

ther of those papers did I have an opportunity to discuss the subject, or I would have brought up the matter then.

It has been stated in the discussion why it is best not to put permanent fillings in young teeth where the pulps are so large and irritation is extremely dangerous. Take the case of a patient of forty-five years, where there is a small approximal cavity, with scarcely any decay about the tooth; also a small cavity in the fissure of the tooth. I had such a case last week, and I filled it, because there was a space where the first molar had been extracted. So small was the space that I contoured it to prevent the molar from coming forward and injuring the articulation. That was an operation where it would have been advisable to cut deeply into the posterior approximal surface, because the contour would have been more graceful. It was much more abrupt to end it where I did than to make that extension. This man was forty-five years old, and there was no caries whatever in that tooth. The tooth was extremely sensitive just beneath the enamel, and rather than extend the cavity, the liability of congestion of a pulp being so great, I made this abrupt extension—not square, of course, but not so beautiful as one built from the cervical margin—so sure was I as to the irritation caused by cutting.

The pulps found in a state of congestion are usually under large gold and amalgam fillings, more particularly beneath large amalgam fillings.

Dr. RHEIN. I understood you to say that you agreed with what I had to say. Under the circumstances, I want to know about this condition of congestion you repeatedly speak of—allaying this congestion. Will you tell us how you do it?

Dr. SHIELDS. I spoke of allaying it when the cavity was first formed. I stated that at the first presence of decay calcified masses have begun to form, and irritation of the pulp has started nearest the spot of irritation. The way to allay it is to excavate all the decay, including all affected enamel, and to insert a non-cohesive filling with a cohesive filling anchored into it.

Dr. RHEIN. How do you know it allays it?

Dr. SHIELDS. From the compatibility of non-cohesive gold.

Dr. RHEIN. You admit that the pulp is diseased after you have capped it. Do I understand that by the placing in of the non-cohesive gold you cure that disease?

Dr. SHIELDS. By cutting the smallest part, instead of mutilating it, you do the best thing for it.

Dr. RHEIN. Do you claim that you bring it into normal condition?

Dr. SHIELDS. No, but in the best condition that is within human power to attain; by having the cavity as small as possible the irritation is bound to be less than otherwise.

Dr. RHEIN. There are numerous cavities from which the patient does not feel any irritation. How do you know that this irritation is allayed? The fact that the filling has become comfortable is no proof. How do you find out that that disease of the pulp has disappeared? I would like the essayist to answer this question upon a practical basis.

Dr. SHIELDS. When a tooth is formed, it certainly is perfect, the enamel cells being first secreted, and the tooth forming from without inward. The less the disturbance to the mechanism from which that tooth was originally made, the better for the tooth. That is the point of the paper.

Dr. RHEIN. You did not examine the pulp microscopically?

Dr. SHIELDS. No; but a small filling will preserve the pulp infinitely better than a large one.

Dr. OTTOLENGUI. The last speaker has just made a statement, which if true I would like to know about. I thought at first that he would not fill those anterior approximal cavities in the first molars with a metallic filling. He now says that he would fill them with a compatible filling of non-cohesive gold covered over with cohesive gold. I am not sure what he means by compatible, and I want to know why a filling which first has some non-cohesive gold and then cohesive gold over it, is more compatible to the tooth than one made altogether of cohesive gold, because I understand the incompatibility of gold is in its high conductivity. Is non-cohesive gold any less conductive than cohesive? Will it conduct heat less rapidly?

Dr. SHIELDS. Yes.

Dr. OTTOLENGUI. You could not prove it in a thousand years.

The Secretary moved a vote of thanks to the essayist for his interesting paper, which was carried.

Adjournment.

WM. B. DUNNING, D.D.S.,
Editor N. Y. Odont. Soc.

PENNSYLVANIA STATE DENTAL SOCIETY.

Thirty-eighth Annual Meeting.

(Continued from vol. xlviii, page 1245.)

CLINICS.

Dr. S. T. CLAY, Philadelphia. "A New Appliance for Spreading the Upper Arch."

Dr. Clay used for this purpose a piece of thin saw-steel, which was fitted to the

cast by filing and bending, after which the steel was tempered to give it the required degree of spring force for spreading the arches. Holes were made in the steel plate into which to engage a clamp forceps when placing the appliance in position.

Dr. CHARLES H. JACO, Philadelphia.
"Gold Fillings."

Dr. Jaco demonstrated the making of several gold fillings, in which soft foil was used for beginning the fillings and cohesive gold for completing them. The clinician laid special stress on preparation of the cavities and on the principle of packing the gold. He also emphasized the advantage of using a soft copper matrix (annealed), in filling all disto-occlusal cavities in bicuspid and molars.

Dr. D. O. M. LECRON, St. Louis, Mo.
"Porcelain Inlays."

Dr. LeCron had an interesting display of cavity preparation for inlay work, which was presented in his characteristic and painstaking manner. Enlarged models illustrating the preparation of difficult cavities with inlays fitted to them were shown, plaster being used to simulate the porcelain and brass the gold. An ingenious arrangement of steps and grooves was used to demonstrate the direction of the forces developed during mastication and the great amount of mechanical retention secured by the clinician's method of cavity preparation.

Dr. C. S. VAN HORN, Bloomsburg.
"Cavity Preparation for Porcelain Inlays, Illustrating Principles Conducive to Retention and Adaptation."

Plaster models were exhibited, in which cavities had been prepared to illustrate the principles employed by the clinician. In cervical cavities the floor was flat or convex, the cervical wall at right angles to the floor, and the wall toward the incisal edge of the tooth was beveled at an angle but slightly greater than a right angle.

Cavities subject to occlusal force had broad flat gingival seats, into which a groove was cut, the labial wall being formed at right angles to the flat axial floor. Inclined planes were so placed that adaption was facilitated, the inlay going to place in the direction in which occlusal force was applied, the greater the force the closer being the adaptation of the inlay to the cavity walls and margin.

It was a noticeable feature that in each instance tooth-structure was depended upon to resist, either directly or indirectly, the occlusal force, cement being used only as a necessary adjunct.

Dr. C. C. VOELKLER, Brooklyn, N. Y.
"A Method of Making Hollow Gold Inlays."

After the cavity has been properly prepared, an impression of it is taken in Perfection modeling compound. From this a die is made either with amalgam, or preferably Whites' inlay metal, the latter being poured directly into the compound impression. The die is invested in "dental lac" in one of the steel cups of the Brewster swaging press. To form the "inner piece," a piece of No. 36 gage pure gold, cut down to within a millimeter of the cavity margins, is swaged over this die. It is now placed in the cavity, a stiff mix of quick-setting cement is made and placed over it, and the patient is told to close the mouth in order to obtain a correct occlusion. A piece of softened compound may also be used for this purpose in small inlays.

The inner piece, with "contour form" of cement or compound in place, is removed from the cavity, and the latter is carved to shape, with proper contour, sulci, etc., but in the restoration of the anatomical form of the tooth allowance should be made for a thickness of gold. No. 34 gage, of which material the "outer piece" will be prepared.

The inner piece and contour form are now replaced on the die, and a piece of pure gold No. 34 gage is swaged over them. This forms the outer piece, which is cut down to within a millimeter of the inner piece.

The three pieces, namely, the inner piece, the contour form, and the outer piece, are now placed in their relative positions in the cavity in the mouth and thoroughly burnished.

The outer piece and contour form are removed, the inner piece is replaced on the die, and a large piece is cut out from its center, thus making a hole through which the solder may be introduced when the two parts of the inlay are in position.

The inner piece is then annealed, placed in the cavity in the tooth, and thoroughly burnished. The piece is now ready for soldering and finishing. Place the inner piece in position on the outer piece, grasp it with fine pliers, put a tiny piece of 22-k. solder, slightly fluxed, in one corner where the two edges of the metal meet, and hold in a Bunsen flame until the solder runs. Repeat this until the two pieces are joined all around with 22-k. solder. Then fill in the hollow with 18- or 20-k. solder to any desired thickness, and finish the inlay roughly on the die. The inlay is then set with cement and finished as a gold filling, care being taken to run the finishing burs, disks, etc., from the gold toward the enamel margins in order to get perfect edges.

The advantages of this method may be briefly summed up as follows: Simplicity; no investing; economy of time—large fillings which would require from ten to fifteen sheets of No. 4 foil may be made, set, and finished in from an hour to an hour and a half; economy of nervous strain on patient and operator, most of the work being done out of the mouth, with no malleting, and a degree of beauty and finish not obtainable in either gold fillings or in most solid fused inlays.

Dr. F. B. HICKS, Brookline, Mass. "Orthodontia Appliances for Expanding the Arch and Regulating the Teeth."

[This clinic consisted of appliances for the expanding of arches and regulating the teeth by the method described and illustrated in *Cosmos* for February 1906, page 185.]

Dr. A. McALPIN, Bradford. "Anchors."

Dr. McAlpin showed several very ingenious methods of using screw posts for the anchorages of crowns for teeth with broken-down roots, and also for the anchorage of large fillings.

Dr. L. M. HOMBURGER, New York, N. Y. "Gold Inlays."

[The method employed by Dr. Homburger for the making of inlays was the

same as that described above by Dr. Voelkler.]

Dr. E. C. JONES, Philadelphia. "The Anesthetizer."

Dr. Jones exhibited an anesthetizer suitable for the administration of any anesthetic. It comprised a combination face-piece, nose-piece, and mouth-piece. The anesthetic by means of this apparatus may be administered through the nose alone, the mouth alone, or through both the mouth and nose. The apparatus is supplied with valves for the admission and control of air during the administration of the anesthetic.

Dr. D. M. HITCH, Philadelphia. "Invisible Bands for the Correction of Irregularities; also Anchor Bands."

Dr. Hitch demonstrated the making of bands for correcting irregularities, covering them with porcelain body to render them inconspicuous. The bands are made of iridio-platinum, soldered with pure gold, and over this high-fusing body is baked, the band having been roughened so that the porcelain will adhere to the metal.

Dr. E. R. SAUSSER, Philadelphia. "Porcelain Veneering."

Dr. Sausser demonstrated the method of porcelain veneering or hooding of teeth in cases of erosion, peg, or "rice" teeth, etc., as suggested by Dr. Chas. H. Land, with a modification in the preparation, viz, the addition of two grooves, one running axially on each side of the teeth, and of an inclined plane on the tip, giving increased resistance to lingual stress. The veneers were built of high-fusing porcelain on a 1/1000 platinum foil matrix. The advantages claimed for this method are as follows:

(1) Nature's joint, that of the enamel and cementum, is left intact, eliminating the accumulation of foreign materials, etc., under the gum, thus maintaining a healthy condition of the gum and giving the tooth-brush full play at the vital point. (2) Easy access to the pulp-chamber, if needed, without destruction of the veneer, it only covering two-thirds

of the crown of the tooth, the lingual surface being exposed. (3) Absence of metal, and therefore greater tolerance by tooth and gum. (4) Strength and durability. (5) Esthetic qualities. (6) Non-destruction of the pulp.

Dr. C. S. BLAKER, Philadelphia.
"Porcelain Inlays."

Dr. Blaker's clinic consisted in the insertion of inlays by the ordinary method, except that he used Ascher's artificial enamel cement for the setting of the inlays.

Dr. WALTER RICHARDS, Slatington.
"Diatioric Teeth in Crown and Bridge Work."

Dr. Richards demonstrated the use of diatioric teeth in bridge work, without the necessity of subjecting them to the flame. His method of making the attachments for the teeth was to burnish a piece of thin platinum into the opening in the tooth, as when preparing an ordinary matrix. This platinum matrix was then filled with moss fiber gold, over which solder was flowed. It was then used in the building of the bridge in the ordinary way, the teeth being cemented into place after the soldering of the entire bridge.

Dr. H. E. HOSLEY, Springfield, Mass.
"Why the Bridge Binds, and a Method to Insure Success."

The clinician claims that the cause for the bridge binding is the shrinkage occurring in soldering, and to overcome this he cuts the cast, and spreads the abutments apart enough to allow for this shrinkage. The size of the space provided for the shrinkage is of course in proportion to the size of the bridge to be made. A groove is made in the bottom of the cast to insure the proper position of the abutments when the cast is again fastened together.

Dr. W. G. CHASE, Philadelphia.
"Porcelain Bridges and Pinless Crowns."

The clinician demonstrated a method of setting pinless crowns by cutting away the back of Davis or other pinless crowns

and fusing porcelain into the space cut away, with a pin set into the crown. He also demonstrated the making of porcelain bridges by the use of Davis crowns or facings attached to a platinum saddle. In using the Davis crowns, the pins are attached to the saddle, upon which the crowns are set after having cut out the backs of the crowns in order to have a good body of porcelain around the pins and crowns. When facings are used, the pins are attached to a continuous bar and the porcelain is built up and carved to the shape of the tooth. Platinum No. 30 gage is used for the saddle. The Davis crowns are first articulated in order to find the position in which the pins are to be set on the saddle. In crown work the platinum is first burnished to the root; the pin is then set, the crown is fitted, and all attached with wax, removed, and invested, care being taken that the pins may be easily removed from the investment. Porcelain body is then packed into the space cut out of the crowns, and the crown is put into the furnace and baked.

Dr. E. J. DONNEGAN, Scranton.
"Repairing Continuous Gum, Gum Sections, and Facings."

Dr. Donnegan demonstrated a method of mending broken gum sections, overcoming the joint between two gum section blocks, etc. His method is to stick the two pieces together with liquid silic, and then fuse the two together in the furnace. Broken facings can be mended in the same way.

Dr. W. M. FINE, Philadelphia. "A Method of Reproducing the Natural Contour of Teeth on the Lingual and Palatal Surfaces of Artificial Dentures."

[This clinic is practically the same as that described in full at page 551 of the DENTAL COSMOS for May 1906.]

Dr. J. E. DUNWOODY, Philadelphia.
"A Way to Obtain Correctly Occluding Cusps for Gold Caps."

After the band for the crown has been made it is put on the tooth, and after placing in it a small amount of model-

ing composition, the patient is instructed to close the teeth. The band is removed, together with the modeling composition, and the cusp is properly carved to articulate with the opposing teeth and to fit the shape of the band. After removing all the composition from the inside of the band, leaving only the cusp to be reproduced, the latter is placed flat side down on a glass slab, and a mixture of two-thirds plaster and one-third medium marble dust is poured over it. After it has hardened, and without using borax, gold is melted into the impression of the cusp until the latter is full, and is then forced down into the impression with a piece of charcoal to insure the copying of every indentation of the cusp. The resulting cusp will be a perfect reproduction of the modeling composition, and will be found to have the exact circumference of the band and to articulate correctly.

Dr. N. H. MYERS, Wilkes-Barre.
 "How to Make a Perfect Joint Between Root and Porcelain Crown."

After preparing the root in the usual way for the reception of a porcelain crown, place a small quantity of base-plate gutta-percha in the root-canal; then heat the dowel sufficiently to soften the gutta-percha and insert it in the root-canal, care being taken to place the crown in proper alignment with the adjoining teeth. After the gutta-percha has hardened sufficiently, gently loosen and remove the crown and pin from the root, thus forming nearly a perfect mold of the pin in the root-canal, which will serve to hold the crown in the same position in the arch at each subsequent insertion. I now take a small strip of carbon paper, the thinner the better, and make a hole through it with the rubber-dam punch sufficiently large to accommodate the pin. By passing the pin through the hole, returning it to the root-canal, and pressing gently on the crown, your carbon paper will show the parts that touch first. By the use of stones or burs remove these darkened spots and bring the crown to place again, repeating this until the carbon shows itself on the entire

surface of the root or crown; then a perfect joint will exist. Whether one wishes to set the crown with gutta-percha or cement, the previously inserted gutta-percha should be allowed to remain intact in the root-canal.

Dr. W. W. MCKAY, Philadelphia.
 "Porcelain Inlay, Using High-fusing Body."

This clinic consisted of the restoration of the mesial half of a lateral incisor, including the cutting edge. The clinic was for the purpose of demonstrating the translucency and lifelike appearance of high-fusing porcelain, the method of shading an inlay from the cervix to the cutting edge, and the cavity preparation for mechanical retention of the inlay.

Dr. W. A. CAPON, Philadelphia.
 "High-fusing Porcelain Carving."

The carving of molars and bicuspid for practical cases is made by using a foundation of platinum which serves as a gage to show the limit of the crown base. After the base is fitted to the face of the root, a layer of porcelain of dark shade corresponding with the natural neck color of the adjoining teeth is first applied, and over this a lighter shade is added, which will give the color of the tooth proper. The carving is now done with a sharp-pointed spatula, and the manipulation is facilitated by mixing porcelain with a gummy substance such as cornstarch or gum tragacanth. The first fusing reduces the original size about one-quarter, but the second addition of material restores the loss from shrinkage, and secures in the reproduction a tooth of natural character, providing the operator has the artistic tendency required for a successful result.

Dr. V. H. JACKSON. "Orthodontia."
 The clinician demonstrated his system of correcting irregularities of the teeth. He showed the method of constructing appliances, first describing the manner of preparing a cast. An accurate cast is made, and the teeth are carved slightly at the neck, which causes the appliance,

when made, to fit closely, thus insuring good anchorage.

The appliance consists of partial clasps, spring clasps, base-wire, finger springs, lugs, etc., assembled on an accurate plaster model, on which they are finally soldered. Spring-clasp attachments retain the appliance in position by grasping the anchorage teeth. They are made by first arranging partial clasps on the lingual sides of the molars and bicuspid used for anchorage. The partial clasps are made of pieces of 18-k. gold plate, No. 36 standard wire gage, contoured to fit the side of the tooth, usually the lingual side. The gold is roughened on the side on which the solder is to be applied.

The spring clasps are of No. 21 or 20 wire, either of gold, silver-nickel, platinum, or German silver. They are shaped to fit the side of the tooth opposite to that against which rest the partial clasps near the gum. The ends of the spring clasps passing over the arch follow closely at the junction of the teeth, and rest on the partial clasps, to which they are finally soldered. A large wire known as the base-wire or body of the appliance is shaped to cross the arch, following the palatal curve, and the ends of the wire are bent at nearly a right angle, forming the "arms." These arms rest on the partial clasps, to which they are soldered with spring clasps. To this anchorage portion of the appliance, springs of any form are united with solder. They are shaped to extend like fingers for moving any of the teeth in the arch as desired.

The base-wire crossing the palatal arch is termed the palatal base-wire; when it follows the lingual curve of the teeth it is termed a lingual base-wire, and when it is arranged to pass on the labial and buccal sides of the teeth in the arch a labio-buccal base-wire.

The method of soldering with chemically pure tin, using the soldering iron, was described.

Casts and apparatus were presented showing the ease with which the arches of the jaws and teeth are equalized with the Jackson appliances and rubber elastics. Casts and appliances of numerous cases were presented, showing the condi-

tions before and after regulating, and the extensive movement accomplished in from two to eight visits.

Dr. W. C. HOEFFER, Pottsville.
"Method of Making Hollow Inlays."

After having prepared the cavity the same as for a porcelain inlay, viz, avoiding all undercuts, and having all margins as nearly at right angles as possible, the edges are then stoned with the Arkansas stone points. This will correct any and all irregular surfaces left by the bur, and at the same time will allow the impression to be withdrawn more readily.

A piece of "dental lac" or modeling compound is now taken and heated, and shaped into a cone, the base of which is chilled in cold water. (Chilling of the base prevents the compound from spreading over the adjoining teeth.) The point being left soft, it is then pressed into the cavity, and held there until it has been thoroughly chilled with cold water. It is now withdrawn from the cavity; if it does not come away readily, or if there be any drawing of the impression, it is the result of undercuts, which must be corrected before proceeding any farther. The impression is now embedded in Melotte's moldine, well lubricated with some thin oil, and the cast or die is poured of S. S. W. inlay metal.

Upon this the matrix may either be burnished, or preferably swaged, using 1/1000 platinum foil. After the matrix has been completed, a mixture of two-thirds silix (fine powder) and one-third plaster and water is mixed to the consistence of putty, kneaded in the fingers, and pressed into the matrix, leaving the matrix in the die. After it has hardened it is carved away sufficiently on the surface to allow for the thickness desired for the inlay, carving from around the margins of the cavity so that an undercut at these points is obtained. This will give to the finished inlay an undercut to which the cement takes hold.

After the core has thoroughly hardened, moss fiber gold is annealed and pressed into the matrix over the core of silix and plaster, and condensed just sufficiently with a broad plugger so that

it will hold. Sufficient moss fiber is now added to restore the contour. At this point the inlay can be placed in the mouth, and the articulation taken, or, if the work be done out of the mouth, it can be placed on a cast and the proper occlusion prepared. It is now invested in the same proportion of silex and plaster as that of the mixture of which the core was made. The exposed edges of the platinum matrix are now coated with an anti-flux just to the margins of the cavity. Gold solder, 22-k., cut in small pieces, is now placed over the moss fiber, and the flame of a blowpipe is applied and solder added until the moss fiber becomes saturated, the moss fiber taking up the molten solder as a sponge does water. It is now taken out of the investment, replaced on the original die, and with a disk it is finished and subsequently polished. The platinum on the under surface of the inlay is now cut away, and the core taken out, the cavity dried and cement placed in both inlay and cavity, and the inlay pressed to place. It is held there until the cement sets, when the filling will be complete.

This method alleviates the strain on both patient and operator, also the unpleasant use of strips and disks in the mouth, which relief I have found to be a great factor from the patient's standpoint; and it is, at the same time, a great saving in material as compared with the solid gold inlay or filling. The method is applicable to any cavity from which a perfect impression can be obtained. In connection with this description, I would like to state that the patients call in the morning, at which time I prepare the cavities, take the impressions, and fill with temporary stopping. Either the same day, or whenever convenient, I have them return to set the inlays one after the other, as it takes only a few minutes to complete the work after the inlay has been made.

Dr. A. D. GRITMAN, Philadelphia.
"Why an Anatomical Articulator Should be Used."

The word prosthesis means replacement; but artificial dentures do not or-

dinarily fulfil all the conditions that are properly implied by that term. We may imitate the natural teeth in size, shape, shade, and arrangement, and thus satisfy the conditions so far as the esthetic part is concerned, but the effort to fulfil the requirements must stop with this.

Important and desirable as the esthetic or cosmetic features of a dental restoration may be, the question of its usefulness is still greater, and therefore the production of an artificial denture which shall restore to the patient the function of normal mastication as nearly as may be possible becomes of first importance. The proper arrangement and articulation does not, as a rule, receive due consideration. The articulation may seem to be right when the teeth are in normal contact, but the moment the mandible is moved in any way, the teeth will have but a single point of contact, the result being that the atmospheric adhesion will be broken, and the teeth instead of being a comfort will be an annoyance to the patient. The using of a full upper and lower denture, especially, is a mechanical operation, and unless the arrangement of the teeth is based upon a mechanical principle, the patient will not derive the maximum comfort from their use.

The face-bow and anatomical articulator, if used properly, make it possible to obtain an articulation that will give at least five points of contact during mastication. Thus the pressure, being distributed evenly over the curves of occlusion, will hold the lower plate in position and prevent the breaking of the atmospheric adhesion in the upper denture. The use of the face-bow is for the purpose of transferring the bite-plates from the patient's mouth to the articulator, so that the casts will bear to the pivotal points of the articulator the same relation as the alveolar border bears to the centers of the temporo-maxillary articulation; thus placing the casts in a correct anatomical relation to one another.

The upper ten anterior teeth are then arranged in relation to the lower bite, and the lower second bicusps are placed in proper position. Next are set, in the following order, the first bicusps, the ca-

nines, the laterals, and the centrals. As each tooth is articulated, the oscillating motion of the articulator is used to determine its correct position. The lower molars are then arranged on a slightly upward curve known as the compensating curve. The upper molars are properly arranged so that when the mandible is thrown forward, and the bicuspid are raised on the points of the cusps, the central incisors and the posterior teeth

will be in contact; then, as the mandible is moved laterally, there will still be at least five points of contact.

Thus, the arrangement of artificial dentures receiving the proper consideration from a mechanical standpoint as well as from an esthetic point of view, the patient will derive the maximum amount of benefit from them, and the replacement will be worthy the name of a prosthetic operation.

EDITORIAL DEPARTMENT.

"THE EDUCATIONAL PROBLEM."

IN this issue appears the paper by Dr. C. S. Butler bearing the above-quoted title, together with the discussion thereon which followed its reading before the Atlanta meeting of the National Dental Association. We dislike to take issue editorially with the views expressed by the author of the paper in question, but as through force of circumstances we were unable to accept his invitation to open the discussion upon the paper at the time it was read, we here take the liberty of expressing an opinion upon the several points raised.

We yield to no man in degree or extent of appreciation of what dentistry has accomplished, in respect for its attainment, or in belief as to its future possibilities as a scientific and humanitarian calling. The story of its achievement is romantic and interesting enough, and the records of the growth of dentistry from its crude beginnings to its present dimensions as an exponent of both science and art are inspiring enough to stand squarely upon their

own foundations of fact, requiring no adventitious aid for their illumination. Hence it is that we think that the author in his opening paragraphs has gone wide of the mark in attributing to the effect of the dental impulse the "marvelous advance in our knowledge of histology, pathology, and kindred sciences, as well as the wide application of antiseptics." For, if it was "men engaged in the study of dental sciences who led the way and gave the impetus to the movement," what becomes of the work of Nasmyth, of Retzius, Pasteur, Koch, Metschnikoff, and the host of scientific minds, medical and otherwise, that were pioneers in the creation and development of our earlier knowledge of these subjects? Or to what place shall we assign the work of Pestalozzi, of Froebel, Seguin, Prang, Krapotkin, Adler, and their co-laborers in the cause of manual training as a means for mind-training? Nor do we agree with the author that the system of instruction now in vogue in dental educational institutions is a peculiar system or of a degree of efficiency "not surpassed in any other field of intellectual activity." Making all due allowances for oratorical effect and personal enthusiasm, this view of dental education strikes us as being rather too roseate in hue, to say the least. Indeed, the defects of the system are apparently the *points d'appui* at which the author's rather radical, not to say revolutionary, suggestions are directed; otherwise why their expressed purpose, as is stated in the beginning of the article, "to effect a complete though perhaps not a perfect change in our entire educational system"?

Dr. Butler's suggestions are four in number. First, he would abolish by gradual absorption and elimination all of our present schools, and substitute therefor dental departments of strong universities with faculties selected by the dental profession. ✖ Second, he would abolish state examining boards, which he regards as being superfluous and of doubtful utility. ✖ Third, he would create a national commission with plenary powers as to location of schools, curriculum of study, and entrance requirements. Fourth, he would provide for general reciprocity among the several states with regard to the license to practice dentistry, by providing that the diploma of his proposed schools, when granted in course and indorsed by the national commission which he suggests, shall be accepted as license to practice in any state or territory in the United States.

These suggestions on the one hand, and the actual situation to be met on the other, seem to us to furnish a striking example of the tremendous hiatus which is popularly believed to exist between so-called theory and practice. The difficulty in this case, as in similar cases which give rise to such an hiatus, is that it is not a theory which is involved, but a suggestion or hypothesis. The obstacles which stand in the way of a practical realization of Dr. Butler's suggestions are numerous, and some of them apparently insurmountable. In the first place, it must be remembered that the group of dental educational institutions which our author proposes to wipe out of existence by a graceful wave of his hand are institutions that have certain vested rights and in the aggregate large property interests. They are conducted by men who are not on the whole animated by utopian ideals, but who while engaged in the work of dental education with at least as much professional pride and interest as those who are endeavoring to make a living at the practice of dentistry, have a natural desire to obtain a reasonable amount of material compensation for their work. Their philanthropy is probably of about normal professional dimensions. They are interested in producing the very best educational result that they can under the circumstances, and among the circumstances is the practical one that they are obliged to find the sinews of war in a financial way in order to carry on the business of dental education. It is therefore practically certain that the owners of these dental educational plants and those engaged in their work could not be induced to fall in with Dr. Butler's project of "gradual absorption and elimination" unless in the course of this metabolic process provision were made for compensating them for the material loss which such a process would otherwise entail. It is doubtless quite probable that in the evolution of events the development of higher educational ideals and the consequent elaboration of the curriculum, with the added cost such elaboration necessitates, will slowly bring about the elimination of the unfit among dental educational institutions, just as evolutionary processes succeed in eliminating the unfit in a biological way. But we think that the factor above referred to, viz, the vested rights and interests of the dental colleges, will continue to act as an insuperable obstacle to any sudden or drastic movement tending to eliminate them or

absorb them otherwise than as the eventual process of evolution shall determine.

We disagree with the author's views with respect to state examining boards and their usefulness. Indeed, we should regard the elimination of the state examining board principle as one of the direst calamities that could befall dental education. It is not the legitimate functioning of the examining board that is of doubtful utility or superfluous; it is the ignorant or mistaken use of the state board principle which is the cause at times of friction. Let it not be forgotten that the state examining board is in principle an executive body, not legislative; the warrant for its activities is the dental statute, and the dental statute is or should be the crystallized sentiment of the dental profession of the state with respect to the qualifications that shall be demanded of the practitioner of dentistry and the limitations which shall surround him in the exercise of his profession in a given locality. The dental profession can have any kind of a dental law that it desires to have, provided always that what it desires is what in the nature of the case it ought to desire; and if the dental law of a state is imperfect, if it does not accomplish what it ought to accomplish, and if the board executing imperfect laws becomes a source of irritation and annoyance to the dental profession, then the said dental profession has no one to blame for the state of affairs but itself. We have repeatedly contended in these pages that the state laws through their executive boards are not a detriment but a help to dental education. The openness of their proceedings, as a rule, and their power to examine into the educational product of the colleges, creates and maintains a most healthy stimulus upon the part of the educating bodies, tending to improve their work and accomplish the definite purpose for which the state dental law was enacted, viz, to protect the public from the baneful effects of incompetent dental practice, which includes likewise the protection of the public from the baneful effects of imperfect dental education. No dental college conducting its work honestly and thoroughly should object to having that work passed upon by a competent board of revision, nor should any right-thinking student object to the additional examination which the state board imposes for license after he has passed the faculty examination for his degree; for in both instances the result is an indorsement of fitness equiva-

lent in character to the favorable report of the bank examiner who has passed upon the condition of a bank and found it to be satisfactory—a result which inspires public confidence and which is in no small degree the warrant for public patronage. Acting under a correctly framed dental law, its board of examiners becomes the connecting link between the dental profession and the dental educational system—the agent of the dental profession, whose duty it is to see that the educational system is efficiently working and turning into the ranks of dentistry graduates who will not discredit it. If the machinery of dental education fails to accomplish this result the fault is in the construction of the machinery or its operation, and not in the principle upon which the creation of the machinery is based.

Dr. Butler proposes to reverse this method and go back to first principles by creating a national commission with plenary powers; that is to say, to get rid of all boards but one and make that a national board. If such a step were feasible, it is a highly debatable question whether the single national board would have any particular advantage over the many state boards, for the reason that it would involve the concentration of power in a small body of men who—be they the best of their kind, the flower of the whole profession—would still be human beings susceptible in their degree to the insidious temptation toward autocracy and that enlargement of the cranium which has been denominated *megalocephalus*, called by the vulgar “swelled head,” and with the temptation, in view of the tremendous possibilities of their powers, to exercise them either in an autocratic, bureaucratic, or faddish way to the detriment rather than to the betterment of the situation.

But one of the functions of this proposed national board, as stated in the fourth suggestion of the author, is that they shall indorse the diplomas of these selected and idealized schools, and that when so indorsed the said diplomas are to be accepted as a license to practice in any state or territory of the United States. We should be glad if it were unnecessary for us to reiterate, as we have many times done in this journal, that the creation of a national board having such powers as Dr. Butler suggests could not be accomplished without an amendment to our federal Constitution for that purpose. The main obstacle in the way of secur-

ing such an amendment to the police power clause of the federal Constitution is that if it were done for dentistry or medicine or any department of the art of healing, it would establish a precedent which would open the door for an interference with the police power clause that would create irresistible antagonisms throughout the nation by direct interference with the so-called states rights. This has been tried and is constantly being tried in other departments which bear directly upon the question of the police powers of the states, and hitherto without success so far as we are aware. In the absence, then, of a constitutional amendment conferring the plenary power that Dr. Butler advocates, the commission could have no power at all, and would be a national commission only in name, with nothing more than a moral status and possibly the force of professional opinion back of it to enable it to carry on its work. Reciprocity, as we have many times pointed out—and we have no reason as yet to change our opinion in regard to that matter—can in the absence of a constitutional amendment only be achieved upon the principle of uniformity of dental legislation throughout the states of the Union. Upon any other basis reciprocity if forced to an issue would result, as was very clearly stated by Dr. L. D. Shepard of Boston in the report of the committee on the address of the President of the National Dental Association at its meeting held in Saratoga Springs, N. Y., in 1892, by “leveling downward rather than leveling upward.”

We have discussed Dr. Butler's paper at some length in order that some of the objections to his plan which seem to us important may be considered in connection with the other points which have been brought out in the discussion thereof, and because we do not wish these suggestions to go forth and possibly give rise to activities based upon the false hope that the difficulties, imperfections, and unsatisfactory conditions connected with dental education and the license to practice dentistry are to be corrected in any such summary manner.

REVIEW OF CURRENT DENTAL LITERATURE.

Conducted by JULIO ENDELMAN, D.D.S.

[*Archiv für Zahnheilkunde*. Berlin, November 1906.]

SOME USEFUL REMEDIES. BY H. W. C. BÖDECKER.

In the communication under the above title, the author discusses among other agents cocain phenate and a preparation which he designates as "zinc iodid." Cocain phenate is prepared by adding to a small quantity of carbolic acid—say about 5 cc.—an equal volume of crystals of cocain hydrochlorid. As soon as the latter are dissolved more cocain is added, until the carbolic acid is saturated. Some undissolved cocain crystals should remain at the bottom of the container, while the supernatant liquid should be perfectly clear, and of a thick syrupy consistence.

Cocain phenate may be used to advantage as an application under the gum before removing deep-seated calculi from the roots of teeth affected by pyorrhea; as an application to relieve the pain caused by the entrance into the mucous tissues of a hypodermic needle; for the relief of pulpitis; to relieve the sensitivity of pulp-remnants after partial extirpation under arsenic; in the treatment of post-extraction pain, ulcers in the mouth, etc., and to diminish the pain caused by ligatures, by clamps, etc. Generally speaking, whenever pain results through injury to the mucous membrane in the course of operations, cocain phenate judiciously applied will be found to be a useful agent, being obtundent as well as antiseptic.

Another remedy to which Dr. Bödecker calls attention is an iodine preparation, which according to his opinion acts better than tincture of iodine, iodine and carbolic acid, or iodine and aconite. For the sake of convenience it has been termed "zinc iodid," although properly speaking it is not exactly that. This so-called zinc iodid was, as nearly as can be ascertained, first recommended by Dr. A. L. Northrop of New York in 1877. It is pre-

pared by mixing a saturated solution of potassium iodid with an equal volume of a saturated solution of zinc sulfate, and iodine crystals to complete saturation are added. The iodine crystals must be added immediately after mixing the two solutions, for otherwise but very little of the pure iodine will pass into solution. The author employs this preparation after the removal of calculi, even in the presence of healthy gum, that the latter may more perfectly adapt itself to the necks of the teeth; whenever the gum is inflamed, appears purplish, and bleeds easily; in the treatment of pyorrhea alveolaris and aphthous stomatitis. In the latter disturbance, if the zinc iodid be preceded by treatment with cocain phenate no pain will follow its application. It has also been found to give satisfactory results in the treatment of sensitive dentin at the necks of teeth, whether due to erosion or caused by the metal clasps of dentures.

SUBLINGUAL LEUCOKERATOSIS. BY DR. J. V. ROY, MONTREAL, CANADA.

The essayist describes the case of a man who sought his services for the relief of a peculiar condition of his mouth. For a period of two years prior to his visiting Dr. Roy, the patient had observed a progressive hardness of the tongue, which, although causing a prickly sensation, did not interfere with mastication or deglutition.

Upon examination it was found that the disease, which had originated in the gum, had now spread to the floor of the mouth. The sublingual mucous membrane on the left side was the seat of a pseudo-cartilagenous degeneration, and the gum on the corresponding side—which was likewise undergoing a similar degenerative change—was covered by grayish bands, which projected beyond the

gingival surface. On the right side, with the exception of a decolorized area of the size of a ten-cent piece, simulating the effect of cauterization with silver nitrate, no pathological sign could be detected. The clinical history and habits of the patient were good. He had never made use of either alcohol—in any of its forms—or tobacco, but his teeth had been badly neglected, many of them having been rendered useless by caries. The case was successfully treated by means of several applications of the galvano-cautery, and the leucokeratosis disappeared completely.

In concluding his communication, the author comments on the obscure etiology of the lesion.

[*Archives de Stomatologie*, Paris, September 1906.]

CONGENITAL FISTULÆ OF THE LOWER LIP. BY DR. A. STIEDA.

The author has observed the case of a young child who presented, in addition to a hare-lip and complete palatal cleft, two small sinuses symmetrically located on each side of the median line. The sinuses opened on the external surface of the lip, and terminated backward in a cul-de-sac under the labial mucous membrane. One of these canals was extirpated and examined microscopically. Its opening and anterior segment were histologically of the same character as the free surface of the lip; while the posterior segment was constituted of elements similar to those of the buccal mucous membrane. These fistulæ are very rare, thus far only twenty cases having been recorded.

The ancient authors, such as Demarquay and Béraud, attributed them to disturbances in the mucous glands during fetal life; while Rose and Madelung traced their pathogenesis to an arrest of development. In their opinion the mandible is developed from two lateral and a median segments, and if the three portions do not become consolidated, one or two fistulæ may result.

Stieda does not accept the developmental theory, for he claims that at no time are there to be found in those locations any canals, such as would be by not becoming united give rise to the formation of sinuses. In his opinion it is due to a faulty development of the lip. It could not be due to a non-

fusion of the two arms of the first branchial arch, for as a matter of fact this arch is from the beginning formed from a single piece, and not by a fusion of its halves. But, on the upper or cranial border of the mandibular arch, at the expense of which the lower lip is formed, there appear at times, as the result of uneven development of the upper border, two, and at other times four, small lobes separated from each other by three sagittal grooves. If the growth of these lobes should be exaggerated, it is easy to understand how they might unite to form the canals observed in the case here recorded. As the grooves extend throughout the thickness of the mandibular arch, when from the latter structure the differentiation of the structures of the lip takes place, the structure of the canals will also undergo differentiation, the anterior portion and external opening assuming the characteristics of the external surface of the lip, and the posterior portion that of the oral mucous membrane.

[*Dental Practice*, Toronto, October 1906.]

A PORCELAIN TIP. BY FRED R. MALLOY, TORONTO.

The author advocates the substitution of the tip of an incisor with porcelain by a method which he describes as follows:

Preparation of the cavity. First square up the edge of the tooth and make it as flat as possible, and with a sharp round bur cut out part of the dentin. Take out the fullest width it will stand without weakening the enamel, and make the walls of the cavity parallel and at right angles with the floor of the cavity.

Matrix and staple. To assist in retaining the tip a staple is used of 24-gage iridio-platinum wire, wide enough to reach the floor of the cavity, and long enough to extend from the cavity about three-fourths the length of the tip. The ends of the staple should be bent outwardly. Cut a piece of 1/1000 platinum foil—well annealed and sufficiently large to cover the end of the tooth—and burnish it over the end of the tooth and into the cavity. The platinum will be punctured in the cavity, but that will only further the ultimate purpose of the method.

Application of the porcelain. The staple is now put in place, and a foundation body, slightly darker than the tooth, is added. The

porcelain is forced into the cavity and enough is put on to cover the ends of the staple. The whole is now carefully dried, removed, and biscuited. After the biscuit bake, care should be taken to see that there is a slight opening between the porcelain and the top of the staple. It can now be put back, re-burnished, and enamel body of the color of the tooth added and fused until the required length and contour are obtained.

[*American Journal of Surgery*, New York, September 1906.]

AN INTERESTING CASE OF CONGENITAL MALFORMATION OF THE MOUTH.

By E. K. MACOMBER, B.S., M.D., AMSTERDAM, N. Y.

The author reports the case of an infant which at birth presented several curious malformations. The first abnormality observed after the birth of the head was a tumor protruding from the mouth. Next a lower incisor was seen. The tumor was found to be about one inch in length and one-half inch in diameter, and was attached to the roof of the mouth opposite the maxillary suture, near its middle point. The tumor was covered with skin and lanugo, and its free end protruded just beyond the lips. The tooth was as perfectly formed as in a child two years of age, except that it was freely movable, there being no alveolar process to support it. On raising the tumor and looking into the mouth, there were found two completely formed tongues, each with a median raphe and a separate frenum, but with a single root. The inner borders of these tongues encroached upon each other in the median line of the mouth, causing their edges to be slightly raised and bringing their under surfaces into apposition for a short distance from their bifurcation. From underneath these edges, and springing from their bifurcation, was a third or rudimentary tongue, which extended down between the other tongues to an equal distance, separating them at their distal extremities, thus giving the appearance of a three-lobed tongue. This median lobe was broader and thinner at its distal than at its approximal end, and had no distinct frenum or median raphe, yet it showed the papillæ on its dorsum the same as the other tongues.

As the mouth was so full that it was

difficult for the child to breathe or receive nourishment, Dr. Macomber removed the tooth, placed pedicle ligatures on the tumor and rudimentary tongue, and removed them at once. After these were removed, a more thorough examination of the mouth could be made, and this revealed two soft palates and two uvulæ. Each soft palate extended upward from the pillars to the median line, where they formed by their union almost a right angle. From the middle of each velum came the uvulæ, extending downward and inward. On each side of the tumor and posterior to the base of it was a groove about one-eighth inch deep, giving the impression that the tumor had sprung from between the maxillary bones, and had prevented their union at this point. Behind this, however, union was complete, and consequently there was no cleft of the palate. On account of the bifurcation of the tongue, the child was unable to nurse, although its attempts were vigorous. Otherwise the child was well formed and weighed six pounds. The tumor was examined and was found to be a lipoma covered with normal skin.

The author operated successfully on the tongue, cutting each frenum and removing sufficient from the inner borders to leave a normal size tongue when united. Before the operation the child was unable to cry aloud, but immediately after the tongue was sutured it could cry as lustily as any other child. Its prospects for being able to talk were good, for the roof of the mouth was in good condition; there was ample room in the pharynx and the tongue was of normal size and shape. Unfortunately, however, the child was taken with whooping-cough, and died at the age of four months and twenty-three days. This is apparently the only case on record of two palates and two uvulæ.

[*La Revue de Stomatologie*, Paris, October 1906.]

ON THE INFLUENCE OF SYSTEMIC CONDITIONS ON CERTAIN SERIOUS COMPLICATIONS OF DENTAL CARIES.

By DR. V. GALIPPE, PARIS, FRANCE.

In the present article Dr. Galippe discusses one of the most important phases of dental pathology, namely, the complications of dental caries as affected by the systemic condition of the patient. The severity of this

class of disorders depends not so much on the intensity of the local infection, as it does upon the constitutional state, i.e. the ability of the human economy to repulse the attack of the invading organisms. He describes several interesting clinical observations of patients in whom the severity of the caries complications were out of proportion to the degree of local infection. From among these observations we republish the following in full, as being a typical portrayal of the pathological phenomena which the author has elucidated:

Multiple abscesses of the face in the region of the neck, presumably caused by the root of a lower molar. In June 1891, he was called in to examine a patient, aged forty years, a restaurant waiter by occupation. Since November 1890 he had been suffering from a series of abscesses, the cause of which up to that time remained obscure. The right side of the face was red and edematous, and presented a number of cicatrices, several of which were fistulous and discharged in abundant quantities pus of a serous character. The orifices of the fistulae were fungous. The eye was partially closed, owing to the presence of an abscess upon the lid. The patient had been in this condition for seven months prior to the examination. The onset of the trouble was marked by toothache, originating in several teeth, and by swelling of the right side of the mandible. The attending physician ordered the application of poultices and of iodin ointment on the painful area, but this treatment was without avail.

Later on he entered the surgical ward of the hospital, and was subsequently operated upon with the view of draining the part. He remained there for ten days, but, as his condition did not improve after leaving the hospital, he was compelled to return six days afterward. He was again operated upon, the operation consisting, as in the previous instance of an incision over the swollen area.

He remained in the hospital a month, but upon leaving, his condition still remained unchanged, and it was only after waiting another month that he decided to follow the advice of his physicians and submit to the extraction of a number of the supposedly offending teeth. This time he likewise waited a month, and finding that no improvement was noticeable, again applied for admission into the hospital, where he remained for several months before coming under the writer's observation. All upper and lower carious teeth had already been removed. Owing to a marked contraction of the masseter muscles, it was found necessary, in order to extract the teeth, to slit the tissues from the commissure of the lips to the anterior border of the masseter. The tissues overlying the maxilla were dissected away, and a number of fungosities were removed from the alveolar groove.

Notwithstanding the number of surgical interventions to which the patient had been subjected, his condition still remaining stationary, his mouth was again carefully examined, this time by Dr. Galippe, who found a small root hidden under a gingival fungosity, which had escaped the attention of the previous practitioners under whose care the patient had been. By means of antiseptic washes frequently applied, the contraction of the masseters was greatly reduced, thus enabling him to remove the offending organ, which proved to be the anterior root of the lower right first molar. After the extraction the patient improved rapidly and eventually recovered.

This case shows plainly what the effects of an alveolar abscess, the result of caries, may be in individuals offering a suitable field for the development of micro-organisms. The patient under discussion was probably an alcoholic, and in addition the state of his health had always been below par.

PERISCOPE.

Soldering Clamp.—The clamp made of iron wire is just the thing to hold two pieces of metal or in wiring a plate. Take iron wire one and one-half inches in length, about No. 16 gage, flatten the ends, and with flat-nosed pliers double-flare a loop at the end.—DR. HASKELL, *Dentist's Magazine*.

To Reduce the Pain Incident to the Removal of Calculi.—For the purpose of reducing the pain incident to scaling, I recommend packing the pocket with a rope of cotton saturated in a one per cent. cocain-adrenalin solution and allow it to remain five minutes.—ELGIN MAWHINNEY, *American Dental Journal*.

Perfectly Swaged Cusps.—After a piece of gold has been swaged into the lead counter-die, remove and anneal it, and place it back in the counter-die, with a piece of rubber dam doubled between the lead counter and the gold. Place the die in position and strike hard. The cusps will be found very sharp and close-fitting. Take care not to get the rubber between the gold and the die instead of between the gold and the lead counter-die.—J. S., *Pacific Dental Gazette*.

Preparing Sensitive Cavities.—A comparatively painless method of cutting away a large body of sensitive dentin consists in running the stones or burs under water. I think that about the most painful thing which could be done to a patient is to run a bur at a high speed in a dry cavity. I am able to do this so-called heroic cutting by running a stream of water upon the bur or stone run at a high rate of speed.—E. J. PERRY, *Dental Review*.

Strength of Tincture of Aconite.—The most important change in the strength of tinctures is that of Tinctura aconiti. This preparation in the U. S. P. of 1890 was directed to be thirty-five per cent. In the U. S. P. of 1900 it has been reduced to ten per cent. It is well to keep this change in mind, for tincture of aconite is an important constituent in liniments used in the local treatment of many diseased dental conditions, especially pericementitis and facial neuralgia.—J. P. BUCKLEY, *Dentist's Magazine*.

Hints to Avoid Wrongly Placing the Cast on the Articulator.—A cast may be placed wrongly on an articulator in various ways, thus: (1) By being placed too far forward or too far back; (2) by being placed so that the plane of occlusion of the teeth will not be directed to the joint; (3) by being placed askew, so that its heels are not equi-distant from the joint adjoining each; (4) and by being tilted, so that the left side is higher proportionately than the right side or *vice versa*. And lastly, the error may be in a combination of one or more of these four malpositions.—STEWART J. SPENCE, *Dentist's Magazine*.

Origin of "Doctor."—The term "doctor" was invented in the twelfth century, about the time of the first establishment of universities. The first person upon whom this title was conferred was Irnerius, a professor of law at Bologna University. The title was created by Emperor Lothair II, but was suggested by Irnerius himself. The term extended to the faculty of theology, and was first given by the University of Paris to Peter Lombard, the famous theologian. In 1329 the College of Asti conferred the first title of doctor of medicine upon William Gordenio.—*Medical Fortnightly*.

Cusps for Bridge Teeth.—Another method of forming cusps on bridge-teeth other than swaging in gold plate, and which I consider much stronger than the latter, is the following: Having the gold crowns on an articulator, grind the facings, and back them with pure gold, as usual flowing a "starter" on the occlusal tip to insure perfect results; after filing the pins more than half in two, and bending over firmly, burnishing a last time to insure perfect adaptation, wax the facings *in situ*, forming all the occluding cusps, and while the wax—Parr's hard wax flux is excellent for waxing all cases to be soldered—is still soft, bring the occluding teeth down into the wax in the normal bite-position; trim the cusps up, as you would for a seam crown, invest—I find three parts yellow ochre and two parts model plaster very good as an investing material, with no hazardous effects—and heat well, being sure to get the case sufficiently hot, and flow your

18-k. or 20-k. solder right into the cusps formed. If properly heated, a few touches with a small carborundum stone will give you pleasing results and a firm, substantial piece of work, with no air-space between the solder and swaged cusps. I find it is always better to leave quite a heavy cusp to take the strain in lieu of the facing. For final polishing of crowns and bridge work I have found nothing more satisfactory than electro-silicon.—**SYDNEY A. SMITH**, *Pacific Dental Gazette*.

Therapeutics of Pyorrhea Alveolaris.—

In all cases of deep pockets, difficult of access, I simplify the work by previously packing the pocket with gauze saturated in twenty-five per cent. phenol-sulfonic acid—or aromatic sulfuric acid will often do quite as well. The packing should be left for twenty-four hours, when the gum will be crowded away from the tooth-neck where the pocket is, so as to enable one to see to a great extent exactly what is being done, and to scale the root without much pain or laceration of tissue.—**ELGIN MAWHINNEY**, *American Dental Journal*.

Treatment for Sensitive Cavities.—

I have frequently been surprised at the results obtained from sealing in a sensitive cavity a preparation of equal parts of oil of cloves and carbolic acid, to which has been added twenty grains of cocain to the ounce. I have found many times that after this preparation has been in the tooth for twenty-four hours, I have been able to prepare extremely sensitive cavities without causing any pain whatever. I do not claim that this will answer in all cases, nor that it is a method to be relied upon to any great extent, but I do know that it is well worthy of consideration, and one which, if followed, will make all cavities less sensitive for exploring purposes.—**W. G. E.**, *Dentist's Magazine*.

Controlling a Hypersensitive Palate When Taking Impressions.—

A gentleman, about sixty years of age, called at my office, claiming that he had been unable to get a set of teeth because no dentist had been able to get the impressions, his throat and palate being so sensitive. The last dentist he had visited, after trying cocain as a spray, and various other methods, told him to go home and tickle his throat with a long feather. This he did, with the result that his stomach and nervous system were in a very bad condition when he applied to me. I was once advised by a physician to use chloretone in such cases. After giving the man the following doses of chloretone, I was enabled to take my

impressions with no unpleasant symptoms whatever. I gave him three powders of chloretone, each containing five grains, and directed him to take them as follows: upon getting up in the morning he was to take one powder; two hours thereafter another, and eat a very light breakfast, after which he was to take the last powder, and report to me. When he arrived at my office I gave him a very small dose of chloretone—say two grains—and proceeded to take my impressions, as I have stated, without the least trouble. The man will sing my praises for doing what so many failed to do, and which they could have done had they only used chloretone. To any one who may ask, I would be glad to recount my experiences in other cases in which I have used this most important compound.—**A. E. FRANKLIN**, *Dental Register*.

Iodin as a Germicide.—In a solution of iodine varying from 0.2 to 1 per cent., we have a very potent germicidal agent, far superior to mercury bichlorid—the acknowledged leader of all other antiseptics. It approaches nearly to the ideal antiseptic in that (a) it is easily prepared and is stable; (b) is non-toxic and non-irritating, in the strength effective, being only one-fourth as toxic as mercury bichlorid; (c) it does not coagulate albumin or form inert compounds with tissues; (d) it is effective in a very brief time; (e) the stain it produces soon disappears; (f) last and most important, it possesses a remarkable penetrating power. A 0.5 per cent. solution is amply strong for all practical purposes.—*St. Louis Medical Review*.

A Few Ideas on "Taking the Bite."—

In "taking the bite" the greatest difficulty to be overcome is the tendency the patient exhibits—apparently from over-anxiety to do the thing right—of protruding the mandible in closing, and this is particularly the case if the term "bite" is used in giving instructions to the patient as to how to close the jaws. Avoid the term "bite," then, and instead, direct the patient to turn the tip of the tongue upward and backward as far as possible. It is well to have the patient do this a time or two before placing the trial-plates in position in the mouth, also after these are in position. Then, when the patient understands what is required of him or her, and the tip of the tongue is back, as far as it can go, direct the patient to "close the jaws." This "upward" and "backward" movement will be found to follow the median line of the vault of the oral cavity directly, as we cannot place the tongue's tip upward and backward as far as possible without follow-

ing the median line, and this overcomes the side bite—either to the left or to the right. It is therefore an inadvertent act on the part of the patient. Moreover, this method brings into requisition all the muscles which are connected either directly or indirectly with the tongue, and I might say that these are many—the genio-hyo-glossus, the hyo-glossus, the stylo-glossus, the stylo-pharyngeus, the middle constrictor of the pharynx, the stylo-hyoid ligament; and even such muscles as the mylo-hyoid, digastric, sterno-hyoid and omo-hyoid seem to be indirectly concerned. All these muscles, by this method, seem to be employed in bringing the mandible into its normal relation to the maxilla, and in so doing they all seem to act together.—W. NELSON CUTHBERT, *Dental Practice*.

The Mixing of Zinc Oxyphosphate Cement.—The problem of mixing a zinc oxyphosphate cement is one which must be largely worked out by the individual operator. One cognizant of the proper feel of the cement beneath the spatula is in position to get good results. In a general way, some points of value can be given. Most often cement does not receive enough of careful spatulation, yet it can be utterly ruined by over-spatulation. Too little spatulation gives a quick-setting, granular result, and over-spatulation gives cement which will never properly crystallize. Thus it can be seen that these features must be kept in mind, and that the operator must become familiar with the proper feel of the cement beneath the spatula.—W. V-B. AMES, *Dental Era*.

A Liquid Preparation of Iodoform.—M. Blanchi has published a formula for the preparation of iodoform in a liquid state which from a therapeutical point of view offers certain advantages over an emulsion of iodoform. It is a syrupy, yellowish liquid, having an odor of iodoform, and is miscible with water, alcohol, ether, glycerin, chloroform, essential oils, benzol, eucalyptol, and creasote. It dissolves guaiacol and several other drugs, and is easily absorbed through the skin, iodine having been found in the urine six hours after the application of the liquid. It is easily prepared by dissolving 35 parts of caustic potash in 25 parts of water, adding first 50 parts of oleic acid and 30 parts of 95 per cent. alcohol, and then 30 parts of iodine in small portions. On warming the mixture, iodine is absorbed, and a brownish liquid is obtained. If necessary, the brown tint may be destroyed by the addition of a few drops of caustic potash. After a few days the liquid is decanted and kept in a dark place.—*Lancet*.

Apply the Forceps Carefully and thus Avoid Serious Mishaps.—One of the errors most frequently made is hastening to apply the forceps as soon as the tooth or root has been condemned to extraction, without making sufficiently careful examination of the case. The fracture of teeth or roots often results from the too hasty and inconsiderate application of force—a mishap that may be avoided by first making a thorough study of the case. Frequently too much force is applied, or too much cutting of the alveolar process, when a testing of the solidity of the root before applying the forceps would have revealed its weakness and perhaps have led to a different method altogether—possibly the elevator instead of the forceps. The careless operator has often felt shame for the heroic bite he has taken with the alveolar forceps to extract a contemptible little stump that he could easily have overturned with the elevator.—*Exchange*.

Little Helps.—When polishing posterior fillings, to avoid scratching the mirror, and to keep tongue and cheeks away while doing the work, I find nothing better than a medium size teaspoon. Insert it always with the concave side toward the surface to be polished, and you will find with what ease the work can be accomplished, and will be surprised at almost complete shutting out of saliva.

After temporary stopping has been inserted in an approximal cavity, take a fine polishing strip, moisten it with eucalyptus oil, and pass it into the embrasure to and fro several times. The filling will become smooth and a better retention will be secured.

A few drops of compound tincture of benzoin rubbed on the hand will prevent the forceps handles from slipping, which they do many times on sultry and muggy days.—GEORGE ZEDERBAUM, *Dental Register*.

The Frequency of Caries and its Relation to the Quality of Bread Used.—It is well known that in all civilized countries carious teeth are extremely common. There is no reason to believe that the evil is greater in Germany and Switzerland than it is here, but it has received much more attention in those countries than here (England). Examinations of a large number of children in elementary schools showed that in Aschaffenburg 99 per cent. of the whole number had decayed teeth, and that on an average the children with such teeth had 33 per cent. of their teeth decayed. The proportions in Berlin were 99 per cent. and 31 per cent.; in Freiburg 99 per cent. and 35 per cent.; in Augsburg in 1904, it was found that only

0.59 per cent. of the scholars had teeth free from decay. The Strasburg authorities examined 4000 scholars in 1903; 97.5 per cent. of the children had decayed teeth, the average proportion of bad teeth being 31 per cent. Bad teeth are not only an effect of wrong conditions, but are also a cause of innumerable other evils. For example, in Strasburg, decay of the teeth was accompanied by swelling of the glands in the neck in 70 per cent. of the children. In 1902 the first German school dental institution was opened in Strasburg for the gratuitous treatment of children's teeth. In the second year of its existence 6900 children had their teeth examined, 4822 teeth were filled, and 6530 were extracted. This systematic examination of children's teeth has led to a striking and very impor-

tant discovery. There is an orphanage for girls in the town, in the dietary of which good hard rye bread forms a part. Some of the girls have been in the orphanage since they were two or three years of age—that is, from an age when they still had their first, or deciduous teeth. These girls have faultless teeth. But some others of these girls had lost their deciduous teeth before they entered the orphanage; they have a considerable number of decayed teeth. These facts seem to prove the soundness of the belief held by a good many observers, that the quality of the permanent teeth depends in great measure on that of the deciduous teeth, and that if the latter are to remain sound, they must be well used.—T. C. HORSFALL, *Dental Record*.

HINTS, QUERIES, AND COMMENTS.

A METHOD OF RESETTING A BRIDGE WITHOUT REMOVING IT FROM THE MOUTH WHERE ONE OF THE ANCHORAGE POINTS HAS BECOME LOOSENED.

Mrs. M. presented herself to me for treatment. On examination I found a bridge extending from the upper right canine to the left canine, and thence to the second molar. The canine roots were supplied with Richmond crowns and the molar with a gold crown. The left canine had loosened and the weight and leverage were so great that the molar had also become loosened and would drop out of the socket as far as the bridge would allow—that being about half the length of the root. There was a profuse discharge of pus from the molar socket. The molar crown was tight to the tooth, and it would have been an impossibility to have split the crown and removed it without risk of the tooth dropping out of the alveolus.

The right canine being tight, I decided to drill through the gold on the lingual surface of the left canine crown. After drilling through the solder and cap of the Richmond, I extracted the loose post and fitted a Justi post through the gold into the canal. After

sterilizing the root and cap, I cemented the post in position, holding the bridge until the cement had hardened. I then drilled a pocket around the end of the post, saturated the same with phosphoric acid, and filled the pocket with quick-setting amalgam. I then began the treatment of the molar socket, using the compressed-air atomizer with a Parke-Davis hypodermic needle as a nozzle, and washed the socket once a day with dioxogen, glyco-thymolin, and campho-phénique. The composition of the formula is as follows:

Campho-phénique,	3j;
Dioxogen,	3j;
Glyco-thymolin,	3iij;
Water,	q.s. ad 3vj.

After twelve treatments the abutments of the bridge were firm and in correct position.

With the small nozzle on the atomizer it is not difficult to reach the apex of the socket, and to wash out all pus and foreign matter, thereby stimulating a healthy granulation. The detachable point of a Parke-Davis hypodermic needle passed through a small piece of unvulcanized rubber and placed in the tip of an atomizer is useful in treating pockets around the teeth, as well as fistulous tracts.

P. NEFF MYERS, D.D.S.

Allegheny, Pa.

OBITUARY.

DR. JOSEPH L. PERKINS.

DIED, at, St. Johnsbury, Vt., March 19, 1906, of heart failure, JOSEPH L. PERKINS, D.D.S., M.D., in his seventy-second year.

Dr. Perkins was the son of Joseph and Lucretia K. (Hovey) Perkins, and was born in Brookfield, February 9, 1835. He was educated at the public schools and Newbury Seminary, and when the Civil War broke out was a student in the medical department of the University of Vermont, from which institution he eventually received the degree in medicine. He enlisted in the First Regiment Vermont Volunteers, and was a participant in the first engagement of the war at Big Bethel, Va.

Choosing dentistry as his profession, he was graduated from the Pennsylvania College of Dental Surgery in 1862. He married on November 6, 1862, Miss Abbie J. Peck of Barre, a sister of the late Rev. Dr. J. Oramel Peck, an eminent Methodist bishop. Dr. Perkins came to St. Johnsbury in 1863, and for over forty years was a successful practitioner of dentistry in that locality.

Dr. Perkins was an enthusiastic and able worker in the ranks of his chosen profession. His professional attainments and general learning were upon more than one occasion suitably recognized and appreciated by his colleagues and co-workers, by intrusting to him the discharge of honorable offices in the several professional associations and secret orders of which he was a member and indefatigable supporter.

He had held membership in the Vermont State Dental Society, and was its presiding officer for several years. He was likewise during several annual terms a member and also president of the Vermont State Board of Dental Examiners.

Dr. Perkins was a contributor to the literature of his profession, his literary productions being on record in several of the dental periodicals of the country. A man of genial temperament and kind disposition, friendly instincts, and sympathetic nature,

the territory of his worldly activities was made brighter by his presence therein.

In passing to his eternal reward he has left in the hearts of friends and acquaintances a vacancy which time will but partially obliterate; but the stimulus of his example will continue to work out its influence in the lives of those who knew and loved him, tempering the sorrow of their loss and strengthening them in those qualities and virtues which make for good and helpful citizenship.

He is survived by his devoted wife, a son, Karl D., a daughter, Miss Isabel W. Perkins, and a sister, Mrs. Charles Cook.

DR. FRANCIS D. NELLIS.

DIED, at Syracuse, N. Y., November 19, 1906, of heart failure, FRANCIS DAVIS NELLIS, M.D.S., in his seventy-second year.

Francis David Nellis was born in the town of Seward, Schoharie county, N. Y. October 1, 1835, of Dutch ancestry. His father, Joseph Nellis, served in the war of 1812, and his mother, Dany Dewey, was a relative of Admiral Dewey.

He began the study of dentistry in the office of his brother, Jacob Nellis, M.D., D.D.S., in Schoharie county, and practiced in Schoharie, Delaware, and Otsego counties prior to his going to Syracuse in 1866, where he was engaged in active work till October 6, 1906.

In early life he married Eva Eliza Gardiner of Schoharie county, who died August 13, 1883. He was a member of the Masonic Fraternity, Syracuse Lodge, No. 501, of the Masonic Veterans of Central New York, and of the Citizens' Club.

Dr. Nellis was a contemporary of Westcott, Palmer, Smith, and Barnes, and a pioneer in the history of the New York State Dental Society, the Fifth District and the Syracuse Dental Societies, and a loved and honored worker in the front rank until the last. A banquet was given in his honor by the Syra-

cuse Dental Society upon the completion of his fiftieth year of dental practice.

He was conservative, steadfast, and consistent, and these qualities, combined with a devotion to the best interests of his chosen profession, made him a source of inspiration to his fellow practitioners, to whom he endeared himself by his genial and friendly nature.

After an illness of six weeks, he died at his home of heart failure, leaving two children—Franklin Dewey Nellis of Auburn, and Mrs. Louie Fritcher of Syracuse—and three grandchildren, Eva Liza Nellis, Theodora and Joseph Nellis Fritcher.

DR. U. D. BILLMEYER.

DIED, at Asheville, N. C., November 24, 1906, in his fifty-second year, U. D. BILLMEYER, D.D.S., of Chattanooga, Tenn.

Dr. Billmeyer was born and spent his youth in Michigan. He was graduated from the State Normal School at Ypsilanti in 1876, and from the College of Dental Surgery of the University of Michigan in 1880. Immediately after graduation he was chosen assistant to the professor of operative dentistry in his alma mater, in which capacity he served with honor and distinction for two years, at which time he resigned to go to a warmer climate in search of health.

In 1883 Dr. Billmeyer settled permanently in Chattanooga, Tenn., and became prominently identified with the business and social interests of that city. His sterling qualities as a gentleman, scholar, and operator soon attracted to him the best and most cultured portion of the community.

Dr. Billmeyer was an unusually skilful operator, and took a leading part in the activities of the dental societies of which he was a member. He was elected president of the Tennessee State Dental Society in 1897, and in 1901 was tendered, and accepted, the chair of professor of operative dentistry in Vanderbilt University, which position he was compelled to resign two years later on account of poor health. Never robust, and fighting from youth that scourge of the human family, tuberculosis, he finally, in 1904, gave up practice, and devoted his time exclusively to a vain search for health.

Dr. Billmeyer loved his profession, and worked always by precept and example to raise it to a higher plane. He was a Knight Templar and a Shriner.

The world has lost in him a valuable citizen, and the dental profession one of its most brilliant and honorable members.

R. M. P.

DR. JAMES OLIVER FLOWER.

DIED, at Pittsburg, Pa., November 8, 1906, after a long illness, Dr. JAMES OLIVER FLOWER, in the sixty-fifth year of his age.

Dr. Flower was born August 17, 1842, in the old Edgeworth Seminary, Sewickley, Pa., which was founded and built by his grandmother, Mrs. Mary P. Oliver. He began the study of dentistry in the office of Dr. Robert Vandervort, one of Pittsburg's oldest dentists.

At the time of the Civil War, Dr. Flower joined the three years' service men, and went to the front. In 1862 he was mustered out on account of illness, and shortly afterward again took up the duties of his calling. After serving an apprenticeship of fourteen years, Dr. Flower became a partner of his preceptor, and subsequently entered upon the career which brought him prominence and professional success.

In 1868 Dr. Flower married Miss S. L. Schinner, who died in 1898. Four children survive him: G. C. Flower, Dr. Will S. Flower, and the Misses Mercedes and Virginia Flower.

DR. RALPH N. BETTS.

DIED, at his home in Sandy Hook, Conn., October 19, 1906, of kidney disease, Dr. RALPH N. BETTS, in the sixty-fifth year of his age.

Dr. Betts had practiced dentistry for many years, but of late, his health having failed, he discontinued his professional work and drifted into commercial pursuits. He was a thorough and conscientious practitioner, and those who knew him realize that in his death they have lost a kind and sympathetic friend. Five sons and one daughter survive him.

SOCIETY NOTES AND ANNOUNCEMENTS.

G. V. BLACK DENTAL CLUB CLINIC.

THE annual Midwinter Clinic of the G. V. Black Dental Club will be held at the Old Capitol building, St. Paul, Minn., on Tuesday and Wednesday, February 26 and 27, 1907.

The clinic committee has prepared the best program possible for it to arrange. The operative clinic and the list of essayists speak for themselves. The list of table clinicians has not been completed. Correspondence with exhibitors leads us to the belief that much which is new will be displayed for those coming from a distance.

Those who are interested in progressive dentistry are most cordially invited to attend our meeting, and take part in the discussion of the clinics and the ideas which will be presented by the essayists.

Special rates are given on all railroads. As there will be other conventions held in St. Paul at the same time, it is suggested that arrangements be made in advance for rooms. The Merchants Hotel and the Ryan Hotel have made a special rate for those attending the meeting. The secretary will gladly reserve rooms for all writing him.

TUESDAY, February 26th, 10 A.M.

Progressive clinic: Gold filling in mesio-occlusal surfaces of upper first molar and upper bicuspids.

1. Dr. A. C. Searl, Owatonna, Minn.
2. Dr. F. S. James, Winona, Minn.
3. Dr. J. W. S. Gallagher, Winona, Minn.

Dr. Wm. Finn, Cedar Rapids, Iowa, will demonstrate the entire method of procedure as followed by these clinicians, using for this purpose a large wooden tooth, clay, etc.

Progressive clinic: Gold filling in mesio-incisal surface of upper canine, lateral and central incisors.

4. Dr. G. N. Beemer, Mason City, Iowa.

5. Dr. W. R. Clack, Clear Lake, Iowa.

6. Dr. F. G. Richardson, Mason City, Iowa.

Dr. F. S. Robinson, Chippewa Falls, Wis., demonstrator.

Progressive clinic: Gold filling in mesial or distal surface of upper canine and lateral and central incisors.

7. Dr. S. Bond, Anoka, Minn.

8. Dr. A. C. Fawcett, Rochester, Minn.

9. Dr. C. H. Robinson, Wabasha, Minn.

Dr. A. M. Lewis, Austin, Minn., demonstrator.

10. Gold filling, occlusal surface of an upper or lower molar, demonstrating use of cohesive and non-cohesive gold. Dr. W. H. K. Moyer, Little Falls, Minn., demonstrator.

11. Porcelain demonstration. Dr. J. O. Wells, Minneapolis, Minn.

12. Amalgam demonstration. Dr. G. D. Moyer, Montevideo, Minn.

Afternoon, 2 P.M.

1st. President's Address. Dr. A. C. Searl.

2d. Report of Clinics.

3d. Essay, "Points of Contact, Their Use and Abuse," by Dr. W. H. K. Moyer.

4th. Essay, "Specific Gravity of Gold Filling," by Dr. K. E. Carlson. (Dr. Carlson will report the results of some experiments which he has made and is still making.)

Evening, 8 P.M.

Illustrated lecture by Dr. G. V. Black, Chicago, Ill.

WEDNESDAY, February 27th, 9 A.M.

The first three clinics are the same as those which will be made Tuesday morning.

Progressive clinic:

1. Dr. C. N. Booth, Cedar Rapids, Iowa.

2. Dr. Wm. Finn, Cedar Rapids, Iowa.

3. Dr. J. V. Conzett, Dubuque, Iowa.

Dr. J. W. S. Gallagher, demonstrator.

Progressive clinic:

4. Dr. J. J. Booth, Marion, Iowa.
 5. Dr. T. F. Cooke, Burlington, Iowa.
 6. Dr. W. G. Crandall, Spencer, Iowa.
- Dr. F. S. James, demonstrator.

Progressive clinic:

7. Dr. S. R. Holden, Duluth, Minn.
8. Dr. A. M. Lewis, Austin, Minn.
9. Dr. F. S. Robinson, Chippewa Falls, Wis.

Dr. W. R. Clack, demonstrator.

10. Amalgam demonstration. Dr. J. B. Pherrin, Central City, Iowa.
11. Porcelain demonstration. Dr. F. S. Yaeger, St. Paul, Minn.
12. Gold inlay. Dr. C. E. Woodbury, Council Bluffs, Iowa.

Afternoon, 2 P.M.

1st. Report of Clinics.

2d. Essay, "The Relation of the Dentist to the Public and to His Patients," by Dr. T. F. Cooke, Mediapolis, Iowa.

3d. Essay, "The Treatment of the Teeth of Children," by Dr. C. N. Johnson, Chicago, Ill.

It is an impossibility to give a list of the table clinicians. A number of men have signified their intention to be with us, and give table demonstrations, which will be of the greatest value to all. This portion of the program has not been completed.

The secretary will be pleased to furnish any information necessary.

R. B. WILSON, *Sec'y*,

Am. Nat. Bank bldg., St. Paul, Minn.

AMERICAN DENTAL SOCIETY OF EUROPE.

The American Dental Society of Europe will hold its next annual meeting in Rome, Italy, on March 29 and 30 and April 1, 1907. A very cordial invitation is extended to members of the profession to be present.

As it is the first meeting of the society in the Eternal City, it is hoped it may be the most enjoyable one in its history.

J. W. GALE, *Hon. Sec'y*,

79 Hohenzollern-Ring, Cologne (Rhine), Ger.

[JAMESTOWN EXPOSITION, NORFOLK, VA.,
1907.]

JAMESTOWN DENTAL CON- VENTION,

TO BE HELD AT

Norfolk, Va., Sept. 10-12, 1907.

Committee of Organization.

BURTON LEE THORPE, St. Louis, Mo., *Chairman*.

H. WOOD CAMPBELL, Suffolk, Va., *Secretary*.

F. W. STIFF, Richmond, Va., *Treasurer*.

R. H. WALKER, Norfolk, Va.

THOS. P. HINMAN, Atlanta, Ga.

J. E. CHACE, Ocala, Fla.

CLARENCE J. GRIEVES, Baltimore, Md.

The Jamestown Dental Convention, to be held under the auspices of the Jamestown Exposition Company, the Southern Branch of the N. D. A., and the Virginia State Dental Association, will convene at Norfolk, Va., September 10 to 12, 1907. The Jamestown Exposition Company have appointed the above named gentlemen as a Committee on Organization, to elect officers in advance of the meeting, to appoint all committees, to finance the meeting, and to bring it to a successful termination.

The Committee on Organization have appointed Dr. Clarence J. Grievess, Baltimore, Md., general chairman of the Clinic Committee and Supervisor of Clinics.

A number of well-known men will assist him on the General Committee. State clinic chairmen have been selected from every state in the Union. The clinics are to be the principal feature of the convention, and it is expected to bring about the largest and most instructive dental clinics ever held. A surgical clinic will also be held under the supervision of Dr. L. M. Cowardin, Richmond, Va. The other members of this committee are J. Y. Crawford, Nashville, Tenn., and A. G. Friedrichs, New Orleans, La. Dr. F. W. Stiff, Richmond, Va., is general chairman of the Membership Committee.

Assistant state chairmen have been appointed from every state in the Union. Already membership fees are being sent in, and

the promise is for the largest gathering of dentists ever held. Only five essays will be read at the convention, one by Prof. W. D. Miller, another by Prof. G. V. Black, and the other three by well-known southern dentists.

Several exhibits of much interest to the profession will be held under the auspices of the convention; among them the dental manufacture exhibit in charge of Dr. John W. Manning, chairman, Norfolk, Va.; a comparative anatomy exhibit, in charge of Dr. W. M. Bebb, chairman, Los Angeles, Cal., which exhibit will consist of three thousand comparative anatomy specimens, and also numerous other collections of interest; a dental historical exhibit, consisting of ancient instruments, operative and prosthetic work, books and photographs, under the chairmanship of Dr. Wm. H. Trueman, Philadelphia, Pa.; the orthodontia exhibit, showing a large collection of models, etc., under the chairmanship of Dr. H. E. Kelsey, Baltimore, Md. The U. S. Naval dental exhibit, showing 3000 charts of the mouths of midshipmen, will be under the chairmanship of Dr. Richard Grady, the U. S. dental surgeon of Annapolis, Md. The exhibit of the U. S. Army Dental Corps, under the chairmanship of Dr. John S. Marshall, San Francisco, Cal., will also show the equipment, method of keeping records, etc., used by the dental corps.*

A full list of the various officers, who are to be elected in advance by the Committee on Organization at their next meeting in February 1907, and of the committees, will appear in due time in the various dental journals. The Committee of Organization is expected to select officers in advance in order that the officers may be prepared for their duties before the actual meeting of the convention.

A cordial invitation is extended to all reputable members of the profession to become members of this convention, and to assist the Committee on Organization in bringing about one of the best, if not the best, dental meeting ever held.

*[Owing to an unfortunate omission in the typewritten copy furnished us by the secretary, the announcement of the convention published in our January issue mixed these two U. S. exhibits, and failed to mention that, as above stated, the naval exhibit will be under the direction of Dr. Richard Grady.—Ed. COSMOS.]

The Exposition itself offers an excellent opportunity for the busy practitioner to take a delightful vacation, see the wonderful historical and naval and military exhibits at the Exposition, and also to participate in this meeting. The membership fee, which is \$5.00, should be sent to Dr. F. W. Stiff, treasurer, 600 East Grace st., Richmond, Va.

A PUBLIC DENTAL LIBRARY IN THE City of Columbus, Ohio.

THE Trustees of the new Columbus Carnegie Library Building, a handsome structure costing \$250,000, have set apart a room 40 by 60 feet for the exclusive use of a Dental and Medical Library.

Columbus being centrally located and of easy access to the majority of the dentists in the state, should be the home of what the dental profession has hitherto been without: a library complete in all the literature of the profession, making it invaluable for research and reference.

The local dentists have organized a Dental Library Association for the express purpose of bringing this matter to a successful issue, and the work thus far accomplished far exceeds our expectations. The Columbus dentists alone have donated \$500 in cash and a number of books and magazines.

To make this library complete in embracing all known works pertaining to our specialty and complete files of all the journals published, we desire the co-operation of every dentist in the state. Any old and rare works, copies of old journals, etc., will be gratefully received, inscribed with the name of the donor, and recorded to his credit in the library catalog. Please communicate with us concerning any literature you may have that you can donate to this cause, giving titles and authors of books; names and dates of journals, etc. In case of duplication they will be valuable for exchange with other libraries.

NATIONAL DENTAL ASSOCIATION.

COMMITTEE ON HISTORY OF DENTISTRY.

Soon after the Buffalo meeting of the National Dental Association in 1905, this committee announced, through the dental journals and otherwise, the exceptional opportunity which had made it possible to place before the dental profession a comprehensive history of dentistry from the earliest times down to the early days of the nineteenth century. Dr. Vincenzo Guerini of Naples, Italy, well known as a dental historian and archeologist, had placed at the disposition of the committee the result of his labors in the field of dental history, which has formed a large and important part of his life-work.

It was the desire of the distinguished author to bring out this book under the auspices of the National Dental Association as a material expression of his appreciation of the contributions which America had made to the progress of dentistry as a profession.

This tribute of the author was sympathetically received by the Committee on History of the N. D. A., not only because of its exceptional merit and the generous sympathy and appreciation which it expressed, but, further, because it furnished in available form and at once the result for which the committee had been created, and for which its members were individually and collectively laboring.

Upon recommendation of the Committee on History, the National Dental Association formally accepted this trust, and pledged its moral support to the enterprise of securing as soon as possible the publication of the work of Dr. Guerini. A thorough canvass of the question from a business point of view disclosed the fact that without a definite, indeed guaranteed market for the book, no publisher could be found willing to undertake the assumed risk of financing the publication, and it was therefore determined by the committee to solicit subscriptions for the work, in order to assure the cost of its publication in advance. Accordingly, and based upon careful estimates, the price of subscription was placed at five dollars per copy, and it was found that not less than 700 copies would have to be subscribed for in advance, in order to guarantee the cost of publication.

By the aid of announcements in the journals, by personal solicitation, and direct ap-

peal by circulars, etc., the present total number of subscriptions received by the treasurer is 400, leaving 300 yet to be obtained before the work of publication can be begun.

The committee asks that all who have not yet subscribed will do so at once. Surely there are enough men in our profession who are interested in its history, and willing to devote five dollars to the securing of such an historical record as has never heretofore been attempted. The matter is ready to put in type, and the book can and will be rapidly put through the press just as soon as the amount necessary to accomplish that end is available for use by the committee.

Send your subscription without further delay to Dr. CHAS. S. BUTLER, treasurer, "The Frontenac," Buffalo, N. Y. Speak of the matter favorably to your colleagues and induce them to do likewise, so that this much-desired object may be consummated without any undue delay. The committee asks that the editors of all dental journals make note of this appeal, and thus lend their important aid to the cause which the committee hopes soon to bring to a successful issue for the benefit of the whole dental profession.

NOTICE TO THE ALUMNI.

ANY alumnus not having received a copy of the souvenir number of the *Pennsylvania Dental Times*, giving the proceedings of the golden anniversary of the Pennsylvania College of Dental Surgery, may secure the same by sending his name and address to

WILBUR F. LITCH, *Dean*,

Eleventh & Clinton sts., Philadelphia, Pa.

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

THE National Association of Dental Examiners will hold their twenty-fifth annual meeting in Minneapolis, Minn., beginning Friday, July 26th, and continuing through the 27th and 29th. A large attendance of delegates is earnestly requested.

Accommodations have been secured in the leading hotel of Minneapolis—The West Hotel. Rates will be as follows: Rooms without bath, \$1.00 per day for each occupant; with bath, \$2.00 per day for one person, and \$1.50 per day for each additional person in room. The hotel is run on the European plan. Any room in the hotel is capable of accommodating two people. All the rooms have telephone connection, and hot and cold water. Railroad rates will be given later.

The Committee on Colleges, Joint Conference Committee, Tabulation of Examining Boards' Reports, and the Committee for Promoting a System of Credits and Uniformity of Examinations will all give exceedingly interesting reports, valuable to all the members of the association.

CHAS. A. MEEKER, *Sec'y-Treasurer*,
29 Fulton st., Newark, N. J.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE forty-third annual convention of the Connecticut State Dental Association will be held at New London, Conn., April 16 and 17, 1907.

An excellent program is assured.

EDWARD S. ROSENBLUTH, *Sec'y*,
1051 Main st., Bridgeport, Conn.

MONTANA STATE DENTAL SOCIETY.

A MEETING of the Montana State Dental Society will be held in Helena, April 12 and 13, 1907.

W. E. TREBISE, *Sec'y*,
Helena, Mont.

ONTARIO DENTAL SOCIETY.

THE eighteenth annual meeting of the Ontario Dental Society will be held in the College Building, Toronto, Ont., February 25, 26, and 27, 1907.

A. E. WEBSTER, *Sec'y Program Committee*,
Toronto, Ont.

ARKANSAS STATE DENTAL ASSOCIATION.

THE Arkansas State Dental Association will hold its annual meeting at Eureka Springs, Ark., May 29, 30, and 31, 1907.

HENRY P. HOPKINS, *Sec'y-Treas.*,
Argenta, Ark.

DETROIT DENTAL SOCIETY.

CLINIC AND BANQUET.

THE twenty-fifth anniversary of the founding of the Detroit Dental Society will be celebrated February 16, 1907.

A splendid program has been arranged, including a clinic, banquet, and a lecture by Dr. C. N. Johnson, the guest of honor, on a subject in which all progressive men are interested—cavity preparation for inlays. A very cordial invitation is extended to all reputable practitioners to attend this meeting.

For any further information apply to

GEORGE F. BURKE, *Sec'y*,
315 Stevens bldg., Detroit, Mich.

NEW YORK STATE DENTAL SOCIETY.

THE thirty-ninth annual meeting of the Dental Society of the State of New York will be held in Albany, May 10 and 11, 1907.

Essays will be presented by the following members of the profession: W. D. Miller, Berlin; A. H. Peck, Chicago; Charles McManus, Hartford; Clarence J. Grieves, Baltimore; G. V. I. Brown, Milwaukee; L. C. F. Hugo, Washington; Nelson T. Shields, New York; I. C. Curtis, Fulton; S. L. Goldsmith, New York (Report of Correspondent); E. Howard Babcock, Brooklyn (Report of Committee on Practice); Emanuel Muntz, Buf-

falo (Report of Committee on Scientific Research).

A full list of clinics is being arranged, and a complete program will be announced later.

W. A. WHITE, *President*,
Phelps, N. Y.
CHAS. S. BUTLER, *Sec'y*,
Buffalo, N. Y.

KENTUCKY STATE DENTAL ASSOCIATION.

THE next annual meeting of the Kentucky State Dental Association will convene at Louisville, Ky., May 20, 21, and 22, 1907. We anticipate a most interesting and profitable meeting. A cordial invitation is extended to the profession.

W. M. RANDALL, *Sec'y*,
Louisville, Ky.

VERMONT STATE DENTAL SOCIETY.

THE thirty-first annual meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 15, 16, and 17, 1907.

The society has in the past held most successful meetings, and we have every reason to expect that this will surpass any previous one, as a very interesting program has been prepared by the committee, and will be mailed in due time. Vermont has the largest per cent. of membership in its state society of any state in New England, and we hope to see every dentist in the state who is eligible a member.

THOMAS MOUND, *Sec'y*,
Rutland, Vt.

SAN FRANCISCO DENTAL SOCIETY.

At the regular meeting of the San Francisco Dental Society the following-named officers were elected for the ensuing year: H. A. Frederick, president; L. V. Levinger, vice-president; L. C. Heller, recording secretary; F. J. Lane, financial secretary; W. A. L. Knowles, treasurer; M. A. Greenlaw, librarian.

L. C. HELLER, *Sec'y*,
San Francisco, Cal.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

THE tenth annual session of the Southern California Dental Association will be held in Los Angeles, May 6, 7, and 8, 1907, at the same time that the Imperial Council of Mystic Shrine meets here, and all members of the dental profession contemplating visiting southern California at that time will confer a favor upon the association by notifying

CHAS. M. BENBROOK, *Sec'y*,
455 S. Broadway, Los Angeles, Cal.

ST. LOUIS SOCIETY OF DENTAL SCIENCE.

CONSOLIDATION OF THE FRATERNAL DENTAL SOCIETY AND THE SOCIETY OF DENTAL SCIENCE OF ST. LOUIS.

At a joint meeting of the Fraternal Dental Society and the Society of Dental Science of St. Louis, held December 18, 1906, a consolidation of the two societies was effected, the consolidated body to be known in the future as THE ST. LOUIS SOCIETY OF DENTAL SCIENCE.

The officers and committees for the ensuing year are D. O. M. Le Cron, president; Richard Summa, vice-president; Clarence O. Simpson, secretary; W. E. Brown, treasurer. Executive Committee—W. L. Whipple, E. E. Haverstick, and Herman F. Cassel. Advisory Council—George A. Bowman, A. H. Fuller, Adam Flickinger, Wm. Conrad, Burton Lee Thorpe, Edward H. Angle, and E. P. Dameron.

CLARENCE O. SIMPSON, *Sec'y*,
457 Century bldg., St. Louis.

IOWA BOARD OF DENTAL EXAMINERS.

THE Iowa State Board of Dental Examiners will hold their next meeting for examination at Iowa City, February 6, 7, 8, and 9, 1907. Candidates will be furnished with proper blanks and such other information as is necessary upon application to the secretary. All applications must be filed with the secretary five days prior to the date of examination.

Address all communications to
E. D. BROWER, *Sec'y*, Le Mars, Iowa.

MASSACHUSETTS BOARD OF REGISTRATION.

A MEETING of the Massachusetts Board of Registration in Dentistry will be held in Boston, March 6, 7, and 8, 1907, for the examination of candidates. Application blanks and further information may be obtained from

G. E. MITCHELL, *Sec'y*,
Haverhill, Mass.

MINNESOTA BOARD OF DEN- TAL EXAMINERS.

THE Minnesota State Board of Dental Examiners will hold its next regular meeting at Minneapolis, in the Medical Building of the State University, on April 2, 3, and 4, 1907. All applications must be in the secretary's hands by 11 o'clock of April 2nd. Candidates will be furnished all necessary blanks and such other information as is necessary, upon application to

GEO. S. TODD, *Sec'y*,
Lake City, Minn.

ARKANSAS BOARD OF DENTAL EXAMINERS.

THE Arkansas State Board of Dental Examiners will hold examinations at Eureka Springs, Ark., May 27 and 28, 1907.

A. T. McMILLIN, *Sec'y*,
Little Rock, Ark.

BOARD OF DENTAL EXAMI- NERS OF CALIFORNIA.

THE Board of Dental Examiners of California held its last meeting in Los Angeles in December 1906, at which time there were forty-seven applicants for examination, of whom twenty-four were successful.

The following officers were elected for the ensuing year: Garrett Newkirk, M.D., Pasadena, president; C. A. Herrick, D.D.S., Jackson, secretary; Joseph Loran Pease, D.D.S., Oakland, treasurer.

The next examination will be held in Los Angeles beginning June 10, and in San Francisco beginning June 17, 1907.

C. A. HERRICK, *Sec'y*,
Jackson, Cal.

ORIGINAL COMMUNICATIONS.

EXPERIMENTS AND OBSERVATIONS ON THE WASTING OF TOOTH TISSUE VARIOUSLY DESIGNATED AS EROSION, ABRASION, CHEMICAL ABRASION, DENUDATION, ETC.

By W. D. MILLER, D.D.S., M.D., Ph.D., Sc.D., Berlin, Ger.

(Continued from page 124.)

(III.)

BEFORE taking up the discussion at the point where it was broken off at page 124 of the February issue of the Cosmos, I wish to correct an error of omission by adding the mucic acid theory of Dr. Cook to the list given on page 2. I beg further to call attention to the case of wasting shown in Fig. 31, where the teeth have been shortened and an open bite produced by the action of the brush and powder. The patient is a man thirty-eight years of age who has always been in perfect health and shows no symptoms of any general malcondition. He *claims* that he brushes his teeth ten minutes at a time twice daily, and uses a French preparation containing a

fair amount of grit. Making all due allowance for exaggeration we may safely estimate the total amount of time spent daily as at least four minutes, which is quite sufficient. That which stamps the case as undoubted wasting is the pronounced wearing of the gold fillings. The filling in *a* is very much rounded off and on a lower level than the enamel. In *e* and *f* both fillings are worn down until they are as thin as paper, and in *f* particularly the gold is worn quite through at one point near the center of the filling, exposing the dentin on the floor of the cavity. A very similar condition can be produced artificially, as in the case shown in Fig. 20 (page 112), where the teeth

were very much shortened by brushing for eighteen hours with a well-known English tooth-paste. In another experiment the teeth of both the upper and lower

FIG. 31.

Shortening of the teeth and open bite produced by immoderate use of brush and powder.

jaws were brushed at the same time, imitating as nearly as possible the manner of brushing practiced in the case shown in Fig. 31, fillings of porcelain, phosphate cement, silicate cement and gold having been inserted. Brushing for thirty-five hours with pumice not only produced wedge-shaped defects in all of the teeth to the first molars, but shortened all of the incisors so as to produce a distinctly open bite, and at the same time removed the greater part of the enamel from the labial surfaces. The porcelain filling withstood the wear much better than the enamel, the cements less well.

Experiments relating to the action of carbonic acid upon the teeth were reported upon in the February issue of this journal. In continuation of the same I found that when carbonic acid was made to bubble through a shallow layer of water from a glass tube drawn out to a fine point, and to impinge upon the surface of a tooth placed one-half inch above

the surface of the water, a very marked action upon the dentin as well as the enamel was observed in four days. (Fig. 32.) The tooth was ground down on one side before the experiment, in order to expose the dentin, and kept moist by a strip of paper hung across it so that both ends dipped into the water. The result is significant with reference to the question whether the carbonic acid exhaled may possibly in the course of years have a slight effect upon the surface of the teeth against which it impinges in mouth-breathing. As already stated, it is but a thought thrown out, and I am not prepared at this writing to say that it is of any particular importance, though it does not seem unreasonable to suppose that, *in conjunction with mechanical action*, as in the case of wasting of the lingual surface of the upper incisors reported in the preceding issue of this journal, a certain effect might be brought about.

We come now to the question: *What are the acids or acid bodies which may be concerned in chemico-abrasion?*

We have the following sources of acids to deal with:

- (1) Acids poured into the mouth with the saliva in certain diseased conditions of the body.
- (2) Acid substances secreted by the glands of the mucous membrane.
- (3) Acids produced by the fermentation of foods.
- (4) Acids produced by the fermentation of mucin.
- (5) Acids taken into the mouth with food or medicine.
- (6) Acid vapors.

(1) It is improbable that any general acid condition of the secretion of the salivary glands can under ordinary circumstances be an important factor in the production of wasting of the teeth. Any such condition would manifest its decalcifying action on all of the teeth, and in particular on those surfaces most exposed to it, that is, on the buccal surfaces of the upper molars and the lingual surfaces of the lower incisors. But these are

places where we very seldom see wasting.

The fact that different authors have come to diametrically opposite conclusions regarding the reaction of the saliva would also seem to indicate that this cannot be an important element in ordinary cases of wasting. Personally I am de-

ing on a bit of non-medicated cotton a few ccm. of saliva may easily be gathered in a clean bottle and the reaction taken. It must of course not be forgotten that the reaction of the saliva varies at different times of the day, and that the alkalinity is most pronounced immediately after eating and is least so when the

FIG. 32.

Decalcifying action of bubbles of carbonic acid on dentin and enamel.

cidedly of the opinion that wasting of the teeth is not necessarily accompanied by an acid reaction of the saliva. In 52 cases in which the reaction of the saliva was taken I found it alkaline in 40, neutral or amphoteric in 10, and acid in 2. I fancy that a great many make a mistake in testing the saliva by simply applying a strip of blue litmus paper to the mucous membrane of the mouth, which nearly always shows an acid reaction. Before making a test of the saliva the mouth should be thoroughly cleansed, or at least rinsed with pure water to remove all particles of food, mucus, and acids produced by fermentation; then, by chew-

stomach is empty. The majority of my tests were made in the forenoon about 11 o'clock; none of them very soon after eating.

In my own case the difference in the reaction of the saliva before and after eating might be called astonishing, as may be seen from the accompanying illustration. It is, however, not always as marked as in this case.

A similar oscillation in the reaction of the urine is said to exist, and it would be well worth while to examine the buccal mucus with reference to the same matter. The few tests which I have been able to make were not conclusive.

Various cases have been reported in dental journals and in text-books on dentistry, under the title "erosion," in which after some severe illness (typhus, gastric disturbance, etc.) a general decalcification of the teeth with wasting of the enamel was observed. These are rare cases which the dentist may meet with once or twice in his lifetime, or not at all. They are due to an intense action of an acid accompanied by the friction of the tooth-brush, and we find the wasting usually associated with more or less softening of the dentin, especially at the necks, or even on the crowns of the teeth.

In this connection we must not forget that a general acid condition in the mouth may lead to a wearing down of the teeth on the morsal surface, as the direct force of mastication is not only sufficient to wear away the disintegrated enamel but also the dentin, decalcified as well as non-decalcified. I have called attention to the fact that while the tooth-brush attacks decalcified dentin less readily than non-decalcified, a hard object such as a wire brush has just the opposite action in that it *tears* away the decalcified tissue more readily. It is well to bear this fact in mind—as well as the inference to be drawn from it, that even softened dentin on the grinding surface may be worn away by the force of mastication acting directly upon it. We see evidence of this in the wearing of the dentin which takes place in the spontaneous healing of caries, although we are not able as yet to say whether changes may not have taken place in the carious dentin which makes it more susceptible to wear.

(2) One of the most difficult and intricate problems associated with the question of wasting of the teeth is the agency of certain acid substances which are said to be produced by the labial glands under certain conditions, and undoubtedly we meet with an acid reaction here much more commonly than in the saliva.

In testing the mucus there are three things to be taken into consideration: (1) The reaction of the fresh mucus; (2) The reaction possibly produced by the fermentation of the mucus; (3) The

modification of the reaction by the fermentation of small particles of food adhering to the mucous membrane. My own mucus, which I have tested some hundreds of times, has an acid reaction at all times of the day. It seems to be capable of undergoing fermentation by which the acid reaction is increased (see DENTAL COSMOS, 1905, p. 1301). I consequently find the reaction strongest in the morning, before rinsing the mouth, and a few hours after meals at which I have eaten soft carbohydrates. I suspect accordingly that my mucus contains at different times different acids, and in different quantities. The reaction is furthermore stronger in the upper than in the lower lip, and *about equal on the lip and on the gums*. In spite of the comparatively strong acid reaction of my own mucus I have been unable to detect any action on the enamel, the only result being a softening of the dentin at the necks of the teeth, and brushing my teeth twice daily *without powder* seems to have no effect on the decalcified dentin and no wasting is produced.

The reaction of the mucus of the upper as well as of the lower lip should be taken by lifting up the lip and inserting a strip of blue litmus paper on one side of the jaw and the red on the other, leaving it there until it becomes saturated. To determine whether the acid comes from the lip or from the gums, insert two pieces of litmus paper separated by any impermeable substance which does not affect the reaction. The reaction should be taken before rinsing the mouth, as in this way only do we obtain true information as to the condition present at the time. If we wish to obtain the reaction of the fresh mucus alone we must of course thoroughly free the parts from all accumulations before making the test. In 52 cases where I made the test after the patient had simply rinsed the mouth I found the mucus alkaline in 8, amphoteric or neutral in 18, and acid in 26. We must not, however, overlook the fact that the mere power of the mucus or saliva to redden blue litmus paper does not necessarily indicate a particularly deleterious action of that mucus upon the

teeth. This depends altogether upon the nature of the acid in the mucus, and as to this our knowledge is at present incomplete. In 26 cases of chronic rheumatism I found 23 with acid mucus. My own mucus is as acid as any I ever met with; and so, too, we find as a rule that the mucus has an acid reaction quite independently of the presence or non-presence of wasting. I have never yet met with a case in which a piece of blue litmus paper inserted between the upper lip and the alveolar process on rising in the morning did not become reddened, and in 25 cases tested at the dental clinic by Mr. Brusen-dorf between one and two o'clock in the afternoon, the mouth not having been rinsed, the litmus was invariably red-dened.

The acidity of the fresh mucus not contaminated by acids of fermentation or otherwise may be due to different causes. It is more particularly the acid sodium phosphate which is looked upon by many as the substance which gives the mucus its acidity and which is respon-sible for chemico-abrasion.

Brubaker (*International Dental Jour-nal*, 1894, p. 742) proposes an ingeni-ous theory to account for the supposed presence of acid phosphates in the buccal mucus. According to him the di-sodium phosphate present in it is converted by carbonic acid into the acid sodium phos-phate and sodium bicarbonate:

The acid sodium phosphate (NaH_2PO_4) brings about a disintegration of the en-amel.

It should be pointed out, however, that NaH_2PO_4 and NaHCO_3 , mixed in the proportions demanded by the formula are rapidly decomposed, with evolution of CO_2 , and a solution results which has no action on either dentin or enamel. On the other hand, there is theoretically no reason for rejecting the suggestion that the acid phosphate alone may be elimi-nated by the glands and the bicarbonate returned to the blood—as has been em-phasized, I believe, by Kirk.

Likewise, Burchard ("Dental Pathol-ogy and Therapeutics"), Truman, Kirk,

and others incline to the view that the acid which may be concerned in wasting of the teeth is secreted by the mucous glands. Under normal conditions the secretion of these glands is often said to have an alkaline reaction, but in the case of certain derangements the secretion be-comes acid owing to the presence of acid sodium phosphate. The acid calcium phosphate has also been detected in the oral secretions under morbid conditions.

The assumption, however, that the secretions of the labial glands have an alkaline reaction under normal conditions seems to rest upon some error of obser-vation. The mucous membrane of the whole mouth will nearly always be found to have an acid reaction at all times of the day, as already pointed out above, and that, too, quite independently of the presence or absence of wasting. This reaction is due in part to processes of fer-mentation going on on the surface, but even after thoroughly rinsing the mouth we find as a rule that the mucous secre-tion reddens blue litmus paper.

Whether this acidity normally present is really produced by acid sodium phos-phate, in whole or in part, we are not able to decide with certainty at pres-ent. According to Kirk it is particularly in morbid conditions that we have to ex-pect the acid phosphates.

With my present understanding of the subject I have some difficulty in recog-nizing the acid sodium phosphate as a potent agent in the process of chemico-abrasion, because of its comparatively slight action upon the hard tissues of the tooth.

A 1 per cent. solution of the acid so-dium phosphate, obtained from the well-known firm of Kahlbaum, Berlin, acting upon a section of a tooth for six weeks at the temperature of the body, did not produce the slightest visible effect on the dentin or the enamel. Likewise a 2 per cent. solution in seven weeks produced so slight an effect even upon the cut sur-face of the enamel that it could only be determined with a magnifying glass.

Also a 1 per cent. solution acting for three months left the surface perfectly smooth and bright. Again, a 1 per cent.

solution dropping from 15-20 hours a day for 10 days upon the ground surface of a tooth showed no effect whatever on either the dentin or enamel.

Finally, a sound tooth kept for over a year in a 5 per cent. solution of acid sodium phosphate was only superficially disintegrated on the external surface.

The acid calcium phosphate has a much stronger action in the same concentration, and for this reason as well as for others to be given later, I should be inclined, of the two bodies, to attribute the greater importance to this one. Attempts to collect the mucus in sufficient quantity to admit of a reliable analysis have up to the present time but imperfectly succeeded, and we shall probably have to depend upon the methods introduced by Michaels and Kirk for the acquisition of a more definite knowledge of the chemical character of the oral mucus under normal as well as under pathological conditions.

A second cause of the acid reaction of the buccal mucus is to be found in *mucin*.

Mucin, an important constituent of the secretion of the mucous glands, is an acid occurring in combination with sodium or calcium or both. It is possible that there may also be free mucin present in the secretion. Its affinity for calcium salts is so slight, however, that it is doubtful whether even when present it has the qualities capable of attacking the enamel. It can hardly, therefore, be looked upon as an agent of importance in the production of wasting, to say nothing of the fact that clinical observations have taught us that wasting of the teeth is not in the majority of cases accompanied by the production of large quantities of mucin.

In my investigations I have found viscosity of the saliva in only 45 per cent. of the cases examined.

(3) Processes of fermentation which take place in particles of food retained between the lip and the upper front teeth lead to disintegration of the enamel and to caries. If the brush and powder were only used vigorously enough to brush away the enamel as fast as it is disinte-

grated, we should in all such cases get wasting instead of caries, but this same brushing would free the surface from food, and for the time being at least stop the fermentation. We can readily understand, however, how a person who brushes his teeth only in the morning, and leaves them subjected to the action of fermenting particles of food over night, might bring about a wasting of the enamel in this way. Likewise, if one whose enamel has become disintegrated on the labial surface, as a result of lack of care of the teeth, should take to brushing with powder, he may wear away the disintegrated tissue and bring about the appearances characteristic of wasting. I have met with a few cases which admitted of an explanation on this basis.

(4) With regard to the very important question as to whether mucin, or the carbohydrate (chitosamin) which forms 25 per cent. of it, is capable of undergoing an acid fermentation, I refer the reader to my experiments reported in the *DENTAL COSMOS* for 1905, vol. xlvii, p. 1301, no further investigations in this line having been since made.

(5) It is a well-known fact that a grape or orange cure may have a most deleterious effect upon the teeth, and Schlenker ("Untersuchungen über das Wesen der Zahnverderbnis," 1882) pointed out that it may produce a condition apparently identical with wasting, provided the teeth are regularly brushed. Two cases came under my notice recently that are sufficiently interesting to merit closer study.

For the first case I am indebted to Dr. Watson of Berlin. An Italian lady, age thirty-one, states that she is in perfect health with the exception of chronic obstipation, and uses the brush moderately with a mild tooth-powder. Her teeth are affected in an unusual fashion, inasmuch as the labial surfaces show peculiar cavities closely approaching a half-circle in shape with the base at the neck of the tooth. These cavities have fairly smooth borders and bottoms, and look

almost as though they had been prepared for porcelain inlays except that they are too shallow. The lingual surfaces of the teeth are completely denuded of their enamel and present a fairly smooth though not shining surface. Similar effects are beginning to appear on the canines and bicuspid. The molars and to a certain extent the bicuspid in the upper jaw are considerably worn down and present cup-shaped surfaces. In the lower jaw the teeth show no defects except a slight wearing down of the incisors and canines.

Examination of the saliva gave the following results: Quantity normal, slimy, strongly alkaline, ammonia weak, chlorids normal, potassium sulfocyanid weak, phosphates under normal, alkaline salts abundant, and among others the basic potassium phosphate. The patient is a vegetarian, eats two or three oranges four times a day, sucking or squeezing the juice out of the segments by pressing them against the upper teeth with the tongue. During the grape season she lives almost entirely on grapes; when these are not to be had, apples, figs, strawberries, etc., take their place.

The other case referred to is similar to that just described. All of the upper front teeth present slight defects (loss of substance) of the enamel, involving about one-third of the labial surface toward the neck. The defects have hard surfaces and are present in the lower teeth in a slighter degree. In this case, too, the patient suffers from indigestion, but shows no trace of gout or rheumatism. He eats six oranges every evening, and occasionally considerable quantities of grapes. Saliva and mucus are very slightly acid. He brushes once a day with powder.

In both these cases I think that there is little room for doubt that the food is responsible in a great measure for the characteristic defects of the teeth.

I have recently met with two cases in which there was *softening of the dentin at the neck of the upper incisors combined with polished defects on the surface of the enamel*. In the one case a neuras-

thenic of forty-five years ate excessive quantities of fruit; there was wasting to a marked extent on both the upper and the lower teeth. At the necks of all the upper incisors the dentin was softened to a depth of about $\frac{1}{2}$ to $\frac{3}{4}$ mm. and showed no wearing away; at the same time there was an evident loss of substance of the enamel, and on the left central a smooth defect about 2 mm. below the cervical margin. In a second similar case of wasting I found softening at the neck of the upper left central where the gums had receded, and a sort of pocket was formed in which particles of food were retained. In both cases the teeth were brushed vigorously, in one with a powder containing about 5 per cent. of pumice.

(6) The action of vapors given off from powerful acids in the production of wasting has been discussed above.

Dr. Cook (*Dental Review*, May 1906, p. 461) following up a suggestion of Mr. McGuigan, comes to the conclusion that mucic acid is an important element in wasting. This acid is presumed to be produced by a complicated series of changes from lactose, and its production is said to be governed at least by enzymes. Or mucin may give rise to mucic acid. It remains to be seen, however, whether mucic acid really occurs in the mouth. By the aid of mucic acid in connection with the mechanical action of a stiff brush, Dr. Cook succeeded in producing wedge-shaped defects at the neck of the tooth, but this experiment hardly proves that mucic acid is really a factor in wasting, especially at the neck of the tooth. We shall await with much interest further reports from Dr. Cook. The results which I personally obtained with mucic acid were similar to those produced by weak solutions of oxalic, tartaric, etc., acids. All of these are similar in their action in that they attack the enamel more vigorously than the dentin, and do not cause the marked softening produced by hydrochloric, lactic, acetic, and other acids. The first two form insoluble compounds with calcium salts, and I suspect that such is the case with mucic acid also.

DIAGNOSTIC VALUE OF FILLINGS.

(a) *Gold and amalgam.*

I have already dealt with the comparative rapidity with which the tissues of the teeth and filling materials are worn down, and have referred to the fact that under the action of acids in conjunction with friction we obtain very different results. This is illustrated by Figs. 33-35.

In Fig. 33 we see the wearing down and slight cupping of a gold filling on

FIG. 33.

Cupping of gold filling on external surface of enamel produced by friction of brush and powder.

the buccal surface of a molar brushed for two hours with pumice.

Fig. 34 is a section of a tooth filled with amalgam and subjected to the action of a 1 per cent. solution of lactic acid, brushed twice daily with chalk for six days. The filling stands here far above the surface of the enamel.

Fig. 35 is a tooth filled with gold and subjected to action of oxalic acid 1:1000 for four weeks, brushed twice daily with chalk. Here again the filling stands higher than the surface of the enamel.

Similar results were obtained with hydrochloric, lactic, and phosphoric acids, 1:1000.

In all cases where we find a gold or amalgam filling standing out above the

enamel surface, as in Figs. 34 and 35, we may be sure that there has been strong acid action upon the enamel; and when, on the other hand, a gold filling is cupped and its surface lies lower than that of the enamel, the acid is very weak or altogether wanting. Naturally a badly condensed gold filling wears faster than one properly made. A case illustrating the above fact was reported by Mr. Hern at a special meeting of the Odontological Society of Great Britain. A patient had been ordered nitro-hydrochloric acid for some acute trouble. He went on taking it for six months. Mr. Hern found all of the gold fillings standing out above the surface of the enamel.

The above criterion may be applied, however, only in case of sound enamel, and where the brush acts at right angles to the direction of the enamel prisms. When the brush strikes the sides of the prisms they wear down as fast as and usually faster than gold without the accompanying action of an acid. This fact, too, is illustrated by Figs. 36 and 37.

The way in which recurrent wasting appears around gold fillings is illustrated by Figs. 38 and 39. A bicuspid was filled with gold on the buccal surface, as seen in the figures. Fig. 38 shows the appearance of the tooth and filling after it had been brushed for five hours with pumice. The enamel and gold wore down with about the same rapidity, the gold a little bit faster, until toward the end of the fourth hour the enamel had become much thinned down and that part lying between the filling and the cervical border was entirely brushed away. The enamel being gone, a deep groove was soon cut into the dentin on the cervical wall of the gold filling, with two horns which extended gradually along the sides of the filling until in six and one-half hours they met in the median line (Fig. 39), thus isolating the filling completely and leaving it projecting considerably above the surface of the dentin.

(b) *Cement fillings.*

The condition of cement fillings in cavities produced by wasting may fur-

nish a valuable indication as to the cause of the process. This fact is illustrated by the case of a woman in the forties,

a small filling of Ascher's cement, one of the new silicate cements, near the neck of the tooth, and that filling is now pro-

whose upper centrals in particular had been suffering from progressive wasting for many years, laying the dentin bare on the labial surface. Three years ago

FIG. 37.

Excessive action of brush and powder on tooth tissue compared with gold filling: (a) filling, (b) enamel, (c) dentin. They were on exactly the same level at the beginning.

I prescribed for her a soft brush and a powder consisting of precipitated calcium carbonate. Notwithstanding this, she as well as the dentist now treating her affirms that the wasting is still continuing. Some two years ago her dentist had made

FIG. 38.

Secondary wasting (abrasion) produced by brush and pumice in four hours.

FIG. 39.

Secondary wasting (abrasion) after six and one-half hours' brushing.

jecting above the surface of the dentin like the head of a pin. It was clear to me that whatever the cause of this continued wasting, it attacked the dentin more rap-

idly than it did Ascher's cement. I accordingly ground away the enamel from the labial surfaces of a number of upper incisors and bored little holes near the necks, filling them with Ascher's cement. On brushing these teeth *with the same brush and powder used by the patient*, the dentin wore down, leaving the filling projecting as described above in one and one-half hours, so that if the patient brushed her teeth but for five or ten seconds a day only she could well have produced the wasting observed in two or three years. Still the question was not disposed of as to whether, after all, some chemical substance may not be active in the process. I accordingly subjected teeth treated as described to dilute solutions of oxalic, tartaric, and mucic acids, to acid sodium phosphate and acid calcium phosphate, also to alkaline solutions: caustic potash and carbonate of potassium. The action of the oxalic acid was particularly remarkable inasmuch as the filling became so disintegrated in twenty-four hours that on passing over the surface with the brush it disappeared totally. Tartaric acid, as well as grape-juice and mucic acid, acted similarly though not so rapidly. In all, however, there was a pronounced solution and wasting of the filling inside of a week. Likewise oxalic acid 1:1000 caused rapid disintegration of the filling. Further, lemon-juice 1 to 4 water, apple-juice, white wine, acid calcium phosphate 1 per cent., formic acid 1 per cent., all caused cupping of filling, likewise stronger solutions of acid sodium phosphate; a 1 to 2 per cent. solution of this salt had but slight effect one way or the other. At the close of the experiment the fillings stood higher than the surfaces of the dentin, but the difference was not so pronounced as where the brush was used alone. Most of the alkalis produced no effect so far as could be determined. These results leave no room for doubt that it is a case of abrasion simply, which is not surprising after all, since we have already seen that precipitated chalk may attack the dentin vigorously.

I would advise the prosecution of similar experiments wherever the opportunity

presents itself, as the results obtained are certainly very instructive and suggestive.

The behavior of tartar in wasting is likewise significant, and may sometimes be made use of as a means of diagnosis. The dark brown or greenish variety of tartar is very tough and resists the action of the brush more stubbornly even than does dentin, but the softer yellowish tartar brushes away more rapidly, and we find that if a tooth whose root is covered with tartar be brushed with powder the tartar will be rounded off on the edges. Where two teeth stand very close together and the space between them is filled out with tartar, it wears away nearly on a level with the dentin, showing perhaps but slight cupping. If we act upon the tooth with a weak acid in the manner usually adopted in my experiments, we shall find the tartar receding much more rapidly under the brush than the dentin. In a number of teeth in my collection the tartar on the root is on the same plane with the surface of the cavity of erosion, and does not show the rounding off that is produced by the action of the brush. These are cases where the wearing away has been produced by some rigid object such as an artificial denture. In other cases the tartar is distinctly rounded off at the margins.

THE RELATION OF RHEUMATISM, GOUT, GASTRIC DISTURBANCES, ETC., TO WASTING.

This relation may best be considered in the present connection, since the supposed causal connection of these disturbances with wasting of the teeth is made to depend upon the vitiated secretions of the salivary or buccal glands.

The majority of authors on the subject of wasting call special attention to the causal connection of gout, rheumatism, arthritis, etc., to the same, without, however, having definitely established the fact that such a relation really exists. Nor is there uniformity of opinion among those who adhere to this view in a general way. Burchard ("Dental Pathology and Therapeutics," p. 249) emphasizes gout in particular as a fruitful cause of

wasting. "Most of the patients have a family history of gout, etc., and very commonly a personal or contemporary family history of rheumatoid arthritis or rheumatism. Even when the existence of rheumatoid or gouty affections is denied by both patient and medical attendant, it is rare that the patient does not complain of some general disorder." Darby, Jack, Kirk, and many others express similar views, while Michaels ("Du Rôle de l'Hyperacidité organique et des Sulfocyanures salivaires dans l'Abrasion chimique des Dents," page 10) writes that in the urinary and salivary analysis of persons suffering from chemico-abrasion the measure (*taux*) of total acidity is less than in the full (*francs*) hyperacids (gouty and rheumatic). From this it would seem that Michaels does not recognize chemico-abrasion as an accompanying symptom of either of these troubles. (Page 18, *loc. cit.*) However, he distinguishes sharply between the dental manifestations accompanying rheumatism and gout. "The arthritic diathesis accounts for (*expliqué*) other manifestations upon the tissues of the mouth—glossy gums, tophi deforming the jaws, pyorrhea, degeneration of the ligaments, agomphiasis, *affections peculiar to the gouty diathesis*." "Among the *rheumatics* the characteristic alterations are entirely different. The acidity of the saliva is in correlation with the sulfocyanid of sodium or ammonium. The local manifestations are—desmodynie alvéolaire, la constriction nerveuse palatale, l'aptyalie ou acrinie salivaire, l'hémodie, l'arthralgie maxillaire, penetrating caries, and *chemical abrasion*."

Then again, page 20: "According to my analyses and observations among the majority of hyperacids the reagents readily show sulfocyanid of ammonium or of sodium, and these may be easily determined in the microscopic preparations. But also among those subjects there is not a trace of chemico-abrasion."

In the "Essai de Sialo-Semeiologie," at page 65, he goes on to say that in the gouty diathesis only traces of the sulfocyanid are to be found in the saliva—by which again he excludes gout, since he

distinctly states that wasting is due to the action of potassium sulfocyanid.

I gather from the above that Michaels recognizes a relation between chemical abrasion and those rheumatics only who have *potassium* sulfocyanid in their saliva.

I am inclined to believe that, on the whole, perhaps too much importance has been attached to gout and rheumatism as predisposing or active factors in the production of wasting. It is true that we frequently find a history of gout or rheumatism, or both in cases of wasting; but these troubles, and especially rheumatism, are so common that I fancy the majority of human beings advanced in years can recall some time or other when they or their forefathers suffered from one or the other of them. Personally I have not found a preponderance of rheumatic or gouty persons among my patients. Of 53 cases in which an examination was made with reference to this question, 6 confessed to gout or showed evident signs of it, 8 were rheumatics, 1 complained of both of these troubles, 6 suffered from some digestive trouble, two of these being at the same time neurasthenics, and 33 denied all personal experience of either gout or rheumatism. In all cases in which wasting was associated with rheumatism or gout observed by me, the toothbrush and some gritty tooth-powder had been made use of in cleaning the teeth, so that it was difficult to determine whether any causal connection existed or not. It accordingly became necessary to examine a number of patients who made no use of brush and powder. In this examination I was assisted by my friend Stanley P. Mummery of London. We examined together, in the hospitals of Berlin and London, 24 cases of gout and 99 of rheumatism, 89 chronic and 10 acute. Among all of these there was not in any single case a trace of wasting, notwithstanding the fact that in many the secretions, as far as could be determined by testing with litmus paper, showed a stronger acid reaction than we find under normal conditions.

There was perhaps more than a usual amount of caries at the necks of the

teeth, but no disintegration of the enamel surfaces.

The cases which I examined personally, 18 gout and 83 articular rheumatism, were all very severe cases of hospital patients, mostly advanced in years and very many of them so deformed by the disease as to be rendered utterly unable to do any work. In 11 cases there were no teeth left, in the remaining 72 the number varied from 2 to 28; the majority, however, being limited to from 6 to 18, and many of those decayed, especially showing much decay at the necks, which were invariably found in a very dirty condition, the tooth-brush never being used.

Professor Riegner of Breslau has recently examined 2 cases of gout and 115 cases of articular rheumatism, all hospital patients, and although he set out in the hope and expectation of finding the defects under consideration, he writes me that the results were absolutely negative.

Now, while the number of cases of gout examined (26) may be too small to admit of drawing a definite conclusion, I think we must agree that the causal connection of this trouble with wasting appears doubtful. Especially, however, is this true of arthritis deformans (articular rheumatism), where the number of cases examined (203) appears to be quite sufficient to establish the conclusion.

In view of these results, I am at a loss to see how we are going to establish an important relation between the arthritic diathesis and wasting. The only escape is to be found in the supposition that if these arthritics had made use of the brush and powder they would have suffered more from wasting than others by reason of the fact that the teeth in arthritis are predisposed to wasting. That this supposition does not lie outside of the range of possibility is shown by the following experiments:

Three teeth were immersed in grape-juice that was kept at room temperature and renewed from time to time; two of them were brushed daily for one-quarter minute without powder in order to determine whether the insoluble crystals which form on the surface of the teeth in con-

junction with the brush might not cause wasting. As the effect produced after two months was only minimal, I began brushing one of the teeth twice a day for fifteen seconds with chalk; one month later the second tooth was subjected to the same treatment. At the end of the fourth month the first tooth was completely denuded of its enamel on the surface where it had been brushed. The second tooth was likewise denuded to a considerable extent. The third (unbrushed tooth) showed a number of chalky spots on its surface, where there was a slight loss of substance; otherwise it appears to have suffered little change. I now brushed this tooth for one-half hour with chalk, this being equivalent to the total amount of brushing received by the first tooth, which was brushed twice daily for fifteen seconds for two months. The effect was scarcely noticeable, and in no way to be compared with that produced on the first and second teeth.

These results seem to justify the conclusion that chemical and mechanical agents acting alternately at short intervals produce much more disastrous effects than when the chemical agent is allowed to act through a long period of time, and the total mechanical action is applied afterward.

On the basis obtained by the results of this experiment one might say that although the teeth of the arthritics examined by me showed no indication of the wasting process, had they been brushed daily a destruction of the enamel might have been brought about in a manner similar to that in the experiment recorded above. I am not prepared to state, however, that I am convinced as to the conclusive nature of this argument. I reserve the right to give a more definite opinion on a subsequent occasion.

IV. ACTION OF SUBSTANCES WHICH ATTACK THE ORGANIC CONSTITUENTS OF THE TOOTH.

As already indicated at the beginning of this series of articles, there are not a few authors of high repute (Znamensky,

Preiswerk, Michaels, A. Bastyr) who break with the historic conception that acids play the paramount rôle in the process of wasting, and who attribute this rôle to substances which attack the organic constituents of the hard tissues of the teeth. It was in the hope of adding somewhat to our knowledge of this phase of the subject that the experiments recorded under divisions IV to VI were undertaken.

(I) ACTION ON SOUND TEETH.

In the *Ohio Dental Journal* for October 1899, under the title "The Effect of Heat on Dentin," I gave the result of experiments showing the effect of temperatures of above 100° Celsius on dentin and enamel. When carious teeth were subjected to higher temperatures than 160° C. for ten minutes the carious parts were completely destroyed and the whole teeth were so brittle as to be easily broken in the fingers. The enamel suffered comparatively but slight change. Znamensky has pointed out that teeth in this condition readily developed defects similar to wasting when brushed, and there can of course be no question that such teeth would yield more readily to mechanical force of any nature whatever than would normal teeth. Of course we never have to do in the mouth with temperatures anywhere approaching the boiling-point, and yet the thought suggests itself that possibly the habit of drinking tea or coffee at temperatures about 70° C. might have upon the teeth a certain deleterious effect of the above nature. It seems, however, very doubtful.

In various communications to this journal—the first in 1890 (*Cosmos*, vol. xxxii, p. 253), I have called attention to the fact that substances which have a strong affinity for organic matter may prove injurious to the teeth by destroying the basis substance and leaving the tooth friable and consequently much more susceptible to mechanical action of any nature whatever. Bone becomes so disintegrated in a 10 per cent. solution of hydrogen dioxid, or in a 5 per cent. solution of caustic potash, that it may readily be

crumbled between the fingers. Sound dentin is likewise acted upon by the same solutions. A block of ivory was suspended for six months, at first in a 1 per cent., subsequently in a 5 per cent. solution of caustic potash. The ivory swelled up and became soft, almost cheesy, so that it could be easily cut with a knife. A chemical analysis gave—Water 26.3 per cent., salts 47.6 per cent., organic matter 26.1 per cent.

A sound human molar was kept for three days in a 1 per cent. solution of caustic potash. The cement in part crumbled away, and its attachment to the root was broken up so that it could be removed *in toto*. Sound teeth were kept in a 5 per cent. solution of caustic potash for three weeks. The roots became brittle and crumbled between the fingers. There was no visible action upon the enamel.

Sections of sound dentin in solutions of 5 to 10 per cent. of perhydrol or hydrogen dioxid became brittle in the course of a few weeks, the solutions being renewed from time to time.

Other less powerful chemical substances seem also to have the power of acting upon the organic matter of the dentin. If we treat ivory turnings for twenty-four hours with a 2 per cent. solution of potassium sulfocyanid the filtrate will give a flocculent precipitate with tannic acid; a similar result will be obtained with a 2 per cent. solution of sodium chlorid or even with water, which shows that all of the substances have the power of extracting *traces* of gluten from the superficial layers of hard dentin. The action is, however, very slight, being highly magnified in the experiments just reported upon, by the comparatively enormous surface of the ivory turnings exposed to the solutions. The solvent action also decreases gradually, and in the majority of my experiments practically ceased in three days. None of these substances act upon the enamel, so far as I have observed.

(II) ACTION ON DECALCIFIED DENTIN.

The action of the above and various

other substances upon decalcified dentin is much more pronounced.

If carious teeth are placed in a 5 per cent. solution of caustic potash or in hydrogen dioxid the carious dentin will be dissolved out, leaving the cavity as clean as though it had been prepared for filling.

Decalcified dentin is readily dissolved in vapors of nitric or nitro-hydrochloric

to pieces in three weeks. All or nearly all of the substances which occur in the mouth were tested in various strengths with reference to their action upon decalcified dentin. The most remarkable results were obtained by the action of solutions of oxalic acid. A tooth with a large cavity on the grinding surface having a thick layer of leathery dentin was

FIG. 40.

A section of decalcified dentin 20 microns thick, undergoing complete dissolution under the action of a 5 per cent. solution of oxalic acid.

acid, or in the vapors arising from the mixture of nitric and sulfuric acid. Five per cent. solutions of sulfuric acid rendered decalcified dentin brittle in eighteen days, while solutions of acetic and nitric acid produced little change.

Decalcified ivory turnings treated for twenty-four hours with 1 to 2 per cent. solutions of caustic potash, hydrogen dioxid, potassium sulfocyanid, or even with common salt, etc., give dense precipitates in their filtrates with tannic acid, as well as a beautiful purple color on treating with caustic potash and a trace of copper sulfate. (Biuret reaction.)

In a 3 per cent. solution of hydrogen dioxid thin sections of dentin crumbled

placed in a test tube with a concentrated solution of oxalic acid, and kept in the incubator. At the end of four days the carious dentin had become quite rotten and could be brushed away with a toothbrush. A 5 per cent. solution of potassium sulfocyanid had a like effect in thirteen days, but this experiment must be repeated. Sections of decalcified dentin 20 microns (1-50 mm.) thick were perforated or completely dissolved in 2 per cent. solutions of oxalic acid in six to eight weeks and in 5 per cent. solutions comparatively sooner. (Fig. 40.)

A slight macerating action on thin sections was manifested also by solutions of potassium sulfocyanid in acid cal-

cium phosphate. Indeed these substances sometimes completely destroyed pieces of decalcified dentin in a few weeks, perforating them in every direction very much as represented in Fig. 41. I noticed, however, in these cases, that the pieces of dentin were subject to a growth about them of a fine mycelium which sometimes escaped notice in the macroscopic examination. This on cultivation proved to be an *aspergillus*. In a few drops of a 1 per cent. solution of lactic acid this organism completely dissolved thin pieces of decalcified dentin in eight days. (Fig. 42.) It seems probable, therefore, that the action which took place in the two solutions last mentioned was due to the *aspergillus* and not to the solutions themselves. In experiments in which the mycelium was successfully avoided the action of the solutions in six weeks was very slight.

Physiological solutions of sodium chlorid, as well as saliva, to which chloroform had been added to prevent bacterial action, showed no dissolution. Sodium sulfate 1:200, ammonium oxalate 1:200, ammonium chlorid 1:200, had no visible action except where a development of bacteria took place. The amount of work necessary in carrying out these experiments was so great that a definite solution of the questions involved could not be accomplished up to the present, but must be reserved for a future occasion. I may say, however, that in no case have I ever observed even such powerful solvents as hydrogen dioxid or caustic potash produce a smooth, polished surface. This can only be brought about in conjunction with mechanical agents, as dealt with under division V.

V. ACTION OF SUBSTANCES WHICH ATTACK THE ORGANIC CONSTITUENTS OF THE TEETH IN CONJUNCTION WITH MECHANICAL AGENTS.

There is scarcely any room for doubt that any substance which has the power of extracting the basis substance from the enamel or dentin, making them thereby friable, would render them more susceptible to mechanical action of what-

ever nature in the mouth, and thus contribute to the production of wasting. This theoretical deduction is confirmed by the results of experiments.

A block of ivory was immersed for one-half its length in a 5 per cent. solution of caustic potash, and daily removed and brushed with 10 per cent. pumice. The part acted upon by the alkali brushed away much more rapidly than the other. Again, the facial surfaces of the teeth of a lower jaw were covered with a thin layer of cotton, which was kept moist with a 10 per cent. solution of hydrogen dioxid for one year and three months. Every day the cotton was removed and the teeth brushed for approximately fifteen seconds with 5 per cent. pumice. Deep grooves were worn in the teeth at the necks, somewhat deeper than according to my experience would have been produced by the brushing without the dioxid. The grooves were typically wedge-shaped, in some cases slightly undermining the enamel. Brush-marks were plainly visible on the surface of the enamel, but I cannot say definitely that they are more pronounced than would have been produced by the brush and powder alone. The enamel margins are sharp, and in two of the teeth more jagged than we are accustomed to see them in natural wasting.

Three teeth in a 5 per cent. solution of caustic potash, brushed twice daily with 20 per cent. pumice for five weeks, showed, on the other hand, no more action of the brush than where the brushing took place with pumice and water only.

In a second experiment, four teeth were fixed in sealing-wax and treated severally with 10 per cent., 5 per cent., and 1 per cent. solutions of caustic potash, to compare with the control, which was treated with water only. All were brushed alike twice daily for from fifteen to twenty seconds with chalk. At the end of six weeks no difference could be detected in the amount of wearing.

We may conclude from the above results that while theoretically the wasting process may be accelerated by all substances that attack the organic matter

FIG. 41.

A section of decalcified dentin about 100 microns thick undergoing dissolution in a solution of acid calcium phosphate in the presence of a mold

FIG. 42.

Action of a pure culture of aspergillus in a few drops of a 1 per cent. solution of lactic acid, on decalcified dentin.

of the dentin or enamel, practically this acceleration is but slight, even where solutions are used which are many times more powerful than any which are found in the mouth. In the mouth itself I am inclined to think that this action is a quantity altogether negligible.

From a teleological point of view it seems highly improbable that compounds normally occurring in the mouth, of whatever nature, have any deleterious effects on the teeth, and in particular on the enamel; we should, furthermore, be forced to expect such effects to appear in excessive degree in the dog, horse, and other animals whose saliva is intensely alkaline as compared with human saliva. Still less probable does it appear that other neutral or indifferent constituents of the saliva have any deleterious effect upon the hard tooth tissue, or take any part in the production of wasting.

The only substance thus far examined to which I am prepared to concede a certain influence in this direction is oxalic acid. Should it really occur in the mouth in appreciable strength, it might well have the effect of rendering decalcified dentin rotten, so to speak, or of assisting in its total dissolution, thereby influencing the character of caries as well as the progress of wasting.

Even sections of hard dentin in solutions of oxalic acid do not undergo the ordinary process of decalcification as produced by other acids, but become rather brittle and rotten, or fall to pieces in a number of weeks, depending upon the strength of the acid and the thickness of the solution. Mucic acid seems to have a similar though less pronounced effect, but I cannot speak definitely on that point at present.

In this connection I wish to call special attention to that mysterious substance to which so much both good and evil in the human mouth has been attributed—potassium sulfocyanid.

THE ACTION OF POTASSIUM SULFOCYANID UPON SOUND TEETH.

Potassium sulfocyanid has been brought into prominence by Michel of

Würzburg, who declares it to be the protecting influence in the saliva against caries, and in particular by Michaels of Paris, who puts it down as the cause of abrasion chimique of the teeth (page 21, "Du Rôle de l'Hyperacidité," etc.). He writes, "Potassium and ammonium sulfocyanids dissolve the ossein of the dental organs and expose the mineral elements, forming with them a calcium sulfocyanid and soluble ammonium and potassium phosphates." On page 20 he writes, "It is this last element (potassium sulfocyanid) which in my opinion is the cause of the process"; and finally ("Essai de Sialo-Sémiologie," page 66): "Potassium sulfocyanid causes wasting." This conclusion of Michaels does not, however, agree with the results obtained by Gautrelet (pages 19, 20, of the "Essai"), who states that in cases of chemico-abrasion the base of the sulfocyanid is not potassium, but *ammonium*. Also in the case shown by Michaels in Fig. 1, Gautrelet found ammonium sulfocyanid in the saliva of the patient (pages 21 and 22).

Personally I have considerable difficulty in recognizing any action of potassium sulfocyanid on sound teeth. I have subjected teeth in every form—whole teeth, halved teeth, sections of teeth—to the action of potassium sulfocyanid in various concentrations for as much as six weeks in succession without the slightest visible effect. Also potassium sulfocyanid 1:1000 applied after the manner described in the experiments of Michaels (page 24) did not have any effect upon the enamel or dentin. A molar was ground down on one side so as to expose the dentin, and 1:1000 solution of potassium sulfocyanid made to drop at the rate of 40 to 80 drops a minute upon the side of the tooth for ten days. This was followed by a solution of double strength—2:1000—for fourteen days, and this again by a solution of quadruple strength—4:1000—for five days. No sign of any loss of substance could be detected at the close of the experiment.

Again, Michaels states that abrasion *chimique* is caused by secretions of the labial glands, but according to Hougouenq the buccal mucus does not contain

any sulfocyanid, nor have I been able to detect it in fifteen different tests where pains were taken to prevent the access of saliva.

Remembering, on the other hand, that potassium sulfocyanid is secreted in particular by the parotid, and keeps constantly trickling down the surfaces of the upper molars, we would expect to find those teeth riddled if potassium sulfocyanid had any eroding action on them. We have here a beautiful experiment going on through life with negative results, which alone seems sufficient to put potassium sulfocyanid as a cause of wasting out of the question.

I doubt very much whether there is any substance in the saliva, either in healthy or diseased conditions, belonging to the group treated under division IV, which materially influences the process of wasting in otherwise sound—undecalcified—teeth. It lies much more within the bounds of possibility that the substances under discussion may, in connection with acids, have a certain influence over the progress of wasting, namely, by dissolving the dentin decalcified by the acid, or at least by rendering it brittle and therefore more susceptible to the action of mechanical agents. This point is more clearly brought out under division VI below.

VI. ACTION OF ACIDS ALTERNATING WITH SUBSTANCES WHICH DESTROY THE ORGANIC TISSUE OF THE TOOTH.

From all of these experimental results it seems that certain substances in the mouth have a macerating action on decalcified dentin, exceedingly slight in most cases, but in some possibly strong enough to merit consideration. An action of this kind would tend to accelerate not only the process of dissolution in the second stage of caries, but also render such thin layers of dentin as may be softened by the action of acids more susceptible to the action of the brush, and thereby accentuate also the process of wasting.

This fact is demonstrated by the re-

sults of the following experiment: A section of the lower jaw containing three teeth was subjected to the action of $\frac{1}{2}$ per cent. solution of lactic acid, alternating daily with a 10 per cent. solution of hydrogen dioxid. In the course of six weeks defects were produced at the necks, extending quite around the teeth. (Fig. 43.) The defects are strikingly similar

FIG. 43.

Action of acid and hydrogen dioxid alternating.

to cases which have been reported of wasting of the approximal surfaces of the lower incisors. (No instance of this has come to my personal notice, in spite of the fact that I have examined over 300 cases of wasting within the last three years.) It is doubtful, however, whether these substances are found in the saliva in sufficient concentration to produce this effect. Further experiments with more dilute solutions are necessary to clear up this question. The fact that thin sections of decalcified dentin are not dissolved in human saliva, so long as it is kept free from bacteria, seems to indicate that under normal conditions this process, if present at all, is reduced to a minimum; under certain pathological conditions, and in rare cases, it may possibly acquire greater importance.

On the whole, I am forced to the conclusion that agents which attack the organic constituents of the hard tissues of the teeth are of very minor importance in the causation of wasting.

VII. ACTION OF FERMENTS IN THE PRODUCTION OF WASTING.

It is a well-known fact that many bacteria produce ferments of the nature of trypsin by means of which they can dissolve albuminous and albuminoid substances in the presence of an alkaline reaction. I have already referred to the views of Arkövy and Preiswerk in relation to this question in the *DENTAL COSMOS*, 1905, vol. xlvii, p. 1294.

Preiswerk inclined to the idea that certain bacteria might produce caries of the teeth by acting upon the organic matter first, instead of upon the inorganic, as the generally accepted theory states. He also is inclined to believe that wasting, particularly at the neck of the tooth, is a kind of caries produced by the proteolytic (proteid-dissolving) power of bacterial enzymes. (*Schweizerische Vierteljahrschrift für Zahnheilkunde*, April 1903, p. 127.)

The question accordingly arises whether bacterial ferments may extract the organic constituents of the enamel or dentin, and so make it brittle or more susceptible to mechanical action. In view of the fact that much more powerful chemical bodies—such as caustic potash and hydrogen dioxid—affect the enamel very slowly, I am of the opinion that the above question must be answered in the negative so far as the enamel is concerned; nor does it seem probable that their action on the sound dentin can be more than very minimal, especially as wasting always occurs at points where there is no accumulation of bacteria. So that I am inclined to exclude bacterial ferments altogether so far as their action on the sound tissue is concerned. The possibility of a certain action on the *decalcified* dentin cannot be denied, particularly as we know that the second stage of caries is for the most part nothing more or less than the dissolution of the decalcified dentin by bacterial ferments. We might therefore conceive that bacterial ferments acting in conjunction with acids would dissolve the dentin as fast as it is decalcified, leaving a hard surface beneath to be kept polished by the friction

of the lips and food. Inasmuch, however, as the surfaces affected by the process of wasting are kept almost absolutely free from bacteria, it is not easy to see how any action of this kind can take place. We know, on the other hand, that whenever the gums begin to grow over cavities of wasting so that food and bacteria may accumulate, the wearing away stops, and we get softening and caries. I see no way at present of establishing evidence in favor of the view that bacterial ferments are factors of importance in the matter in question.

VIII. ELECTRICAL ACTION IN THE MOUTH AS A CAUSE OF WASTING.

I have thus far been able to obtain no evidence in support of the theory that wasting is caused by the electrolysis of the salts contained in the oral fluids. The following experiments were made: A bicuspid was connected by means of a platinum wire, bound around the crown near the neck, with the positive pole of a Siemens battery of 3 units, and another bicuspid in the same way with the negative pole. The teeth were now dipped into the two arms of a U-shaped tube filled with a physiological solution of common salt. On closing the circle a galvanometer having a multiplier of 1000 turns and a resistance of 200 Siemens units showed a deflection of 31°; at the end of two weeks this deflection amounted to 8°. During this time a groove about $\frac{1}{2}$ mm. deep had been eaten into the neck of the tooth connected with the positive pole; the other tooth showed no change. This experiment was made in the year 1881, and reported in the *Deutsche medizinische Wochenschrift*, No. 29.

In a second experiment recently made, a battery of 3 dry cells was used, and the experiment continued in the same way for two weeks. In this case the platinum wire had eaten its way through the enamel, and had caused considerable softening of the dentin. This was only the natural effect of the chlorin which is liberated upon the surface of the tooth in contact with the platinum wire. The

result was simply decalcification. It is possible that by modifying the experiment so that the current passes through a solution alternately in opposite directions, the tissue, in this case decalcified by the chlorin, might be destroyed by the caustic soda liberated on reversing the current. I have had as yet no opportunity of performing this experiment.

TREATMENT OF ABRASION AND CHEMICO- ABRASION OF THE TEETH.

The treatment may be either therapeutic or prophylactic, or both. The therapeutic treatment consists in restoring the lost portions by means of porcelain or gold, and occasionally amalgam. Porcelain fillings protect the surrounding tissue better than gold. Pink gutta-percha, otherwise an excellent material, is debarred by its color and by the difficulty of anchoring it in shallow smooth-bottomed cavities.

In deciding upon the prophylactic treatment to be adopted we must be guided by the results of the examination as to whether it be a case of abrasion only, or of chemico-abrasion. We must determine also whether the process is one of long standing or of recent origin, and the rate at which it is at present progressing.

We examine the tooth-powder and the brush, and inform ourselves as to the manner in which the teeth are brushed, whether once or more daily; how long at a time; how often powder is used; whether the brush is dipped once into the powder or several times; the amount of pressure applied, etc. The teeth should be dried and examined with a magnifying glass, and the appearance of the surfaces carefully noted. Particular attention should be given to the condition of old fillings.

The treatment consists in prohibiting the use of all gritty powders or pastes, and limiting the use of other powders to once a day, or, where the enamel has been destroyed, to three times a week. The brush without powder may be used

after every meal, or as often as may be necessary in order to keep the teeth free from particles of food.

If evidences of acid action (chemico-abrasion) are present from whatever source, it should be counteracted by such means as are indicated in each individual case. Usually the free use of sodium bicarbonate or milk of magnesia may have a beneficial action, and if the acid condition results from some systemic derangement the treatment must be directed at the same time against the latter. The tooth-brush should be sparingly used and tooth-powders avoided during recourse to grape and similar cures.

I have attempted in the foregoing series of communications to make an absolutely objective presentation of the results of observations and experiments which I think everyone will acknowledge to be exceptionally extensive and painstaking. The great difficulties which are encountered in dealing with many problems relating to the pathology of the teeth and contiguous parts were encountered here in full measure. For this reason it will be readily understood that it was not possible to present a definite answer to many of the questions which came up in the course of the work. I trust, however, that the workers in this particular field—of whom there are many at present in America—may find some help in my pages, as I have found in theirs.

I propose to return to this subject later, after the mass of evidence which has been accumulated has become more thoroughly digested.

I wish to express my indebtedness to all who have done good work in connection with the study of wasting, especially to Drs. Truman, Darby, Kirk, Burchard, Zsigmondy, Bastyr, Cook, and a host of others; also to those who have made it possible for me to examine an exceptionally large number of cases in practice: Drs. Abbott, Barrows, Brausewald, Davenport, Dentz, Freund, Frohmann, Gordon, Grevers, Hayden, Heydenhauss, Jenkins, Körbitz, Hielscher, Mamlock, Stanley, Mummery, Pulvermacher, Rieg-

ner, Rosenberg, Schramm, Ramsey, Watson, Watling, Wittkowsky, Warnekros, York.

I deduce the following conclusions from the results of my investigations:

CONCLUSIONS.

(1) Wasting of the teeth is for the most part a purely mechanical process (abrasion), in which the chief and often only factor concerned is the tooth-brush in conjunction with tooth-powder. While all powders or pastes containing pumice, cuttlefish bone, or oyster-shell are particularly injurious, excessive brushing with milder preparations may severely abrade the dentin, and in the course of years even the enamel. Abrasion may be readily produced artificially by the action of brush and powder.

(2) By far the great majority of cases of so-called wasting of the lingual surface of incisors and canines are produced by the friction of artificial plates or clasps.

(3) It has not been conclusively proved that wasting may occur, even in isolated cases, without the use of the tooth-brush or some corresponding mechanical agent.

(4) Coarse foodstuffs, under ordinary circumstances, as well as the crystallized salts of the saliva in general, are factors of but very minor importance; likewise the friction of the mucous membrane.

(5) Acids in general, especially in the strength in which they occur in the mouth, cannot produce wasting. They decalcify the tissue, rendering the enamel chalky and friable, and the dentin soft. Further than that their action does not go. Erosion in other words is never identical with wasting. Only vapors of powerful acids—strong nitric acid, mixtures of nitric and sulfuric acids, etc., which attack the organic constituents of the tissue about as readily as the inorganic—can produce effects resembling wasting with a minimal amount of friction.

(6) Acids in motion—running, trickling, dropping—act much more intensely on the enamel than acids at rest. Carbonic acid attacks both dentin and enamel vigorously.

(7) Enamel which has been disintegrated by an acid becomes thereby much more susceptible to wearing by mechanical agents. Decalcified dentin, on the other hand, is less susceptible than normal.

It results from this that wasting of the enamel is accelerated by the action of acids, *i.e.* chemico-abrasion of the enamel is more readily produced than simple abrasion. Wasting of the dentin is not accelerated by the action of acid; it may even be retarded or prevented altogether.

(8) Only those acids, however, that have a strong decalcifying power over the dentin retard wasting; oxalic and tartaric acid, and possibly certain others, are devoid of this action. Whether the acid only dissolves the calcium salts of the tooth or decomposes them, and whether it forms soluble or insoluble compounds with them, probably influences their action materially.

In order to produce wasting under the influence of acids a certain relation must be maintained between the mechanical and chemical action. If the latter predominate, we get decalcification and caries but not wasting, or we may have both occurring side by side.

(9) Under the continued action of an acid the repeated application of friction at short intervals produces more effect than the application of the total amount of friction at one time.

(10) There is no specific acid concerned in the production of chemico-abrasion. Any acid occurring in the mouth—that is, any which has the power of attacking the enamel—may take part in the process.

(11) Chemico-abrasion differs from abrasion in its greater tendency to attack the enamel of the teeth.

(12) Destructive processes sometimes observed in connection with typhus, chronic gastritis, etc., or as a result of excessive use of grapes, lemons, or sour oranges, or of the injudicious use of acid medicines, assume a character more or less resembling chemical abrasion, provided the brush and powder are diligently employed.

(13) The relative rapidity with which

the different tissues of the tooth wear away in comparison with fillings may furnish a means of determining whether we have to do with a simple case of abrasion, or whether an acid is concerned in the process (chemico-abrasion).

(14) Substances that attack the organic constituents of the teeth (heat, hydrogen dioxid, strong alkalis) make the teeth friable and consequently more liable to wear by friction. The effect of alkalis occurring in the saliva is, however, exceedingly slight, if indeed it can be said to exist at all.

(15) The substances enumerated under 14 have a much more pronounced effect upon decalcified dentin. Likewise oxalic acid—and possibly to a slight extent certain other substances enumerated—disintegrates sections of decalcified dentin in the course of time, and when present in appreciable quantities may,

apart from its decalcifying action, influence the progress of caries as well as that of chemico-abrasion.

(16) Substances which attack the organic and anorganic constituents of the dentin alternately may produce wasting with a minimal application of mechanical action.

(17) I was not able to find any action on the part of potassium sulfocyanid, either in producing wasting or in predisposing the teeth to it.

(18) The connection between the acid diathesis—in particular gout and rheumatism—and wasting, does not appear to be as intimate as has generally been supposed.

(19) No satisfactory evidence has been produced up to the present in support of the view that bacterial enzymes or electrolytic processes perform an important rôle in wasting of the teeth.

TREATMENT OF PYORRHEA ALVEOLARIS.

By GORDON WHITE, D.D.S., Nashville, Tenn.

(Read before Section III of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

I ESTEEM it an honor to be asked to tell how I cure pyorrhea alveolaris, since we have many gifted men in our association who have done so much in the line of pathology and treatment of this destructive disease. I bring to you no untried theories, but will briefly describe the treatment which has given me the results which I will later place before you on the screen.

No disease with which we come in contact so absolutely baffles our skill and has its own way in ridding our patients of their teeth and health as does pyorrhea. I think I state a fact when I say that the larger percentage of our profession say unequivocally to their patients, "It cannot be cured; you will lose your teeth." Any other statement to patients

who continually do those things which lower their vitality—such as overeating, using alcoholic drinks and tobacco, or who are indifferent to the hygiene of their mouths and disregard serious functional disturbances, such as intestinal indigestion, etc.—would be reckless in the extreme, and would place a man who has promised a cure in a most embarrassing position toward his practice; yet one might as well say that tooth-decay or malaria cannot be cured under treatment and changed conditions.

Few there are, if any, among us who have not seen clearly manifested in the gums the effect of nearly all constitutional lesions or auto-poisoning, of whatever nature. Any lowered vital or abnormal condition is shown in the

mouth, and there is scarcely any pathological condition that an inflamed or suppurating condition of the mouth will not accelerate or produce.

Indeed, in its poisoning effects it works as automatically as does any law of mechanics.

My observation is that nearly all the gum troubles lead to pyorrhea, and in its treatment, even before a thorough examination is made, the mouth is mopped, sprayed, or rinsed with some antiseptic, such as dioxogen, for cleansing. Afterward a general and thorough examination with a smooth instrument is made of all the teeth so affected, and treatment is begun upon the most important ones, or those most involved, by applying to the gum and injecting into the pockets any one of the reliable local anesthetics, and after a few minutes removing the deposits with a rigid, delicate instrument. The success of this operation, in many instances the most delicate in the field of surgery, is greatly dependent upon the thoroughness with which it is performed, for the thin layer of what is commonly called serumal calculus can rarely be seen, and yet can be scraped to an infinitesimal thinness, even with well-adapted instruments, without its removal being accomplished. For do what we may in the treatment, surgically and medicinally, so surely as any of the deposits remain, just so surely will every effort at cure meet with failure.

During the surgical operation of removing these deposits, the patient is permitted at intervals to rinse the mouth thoroughly with some antiseptic wash, the anesthesia being kept up by dipping the instrument in use in a few drops of the anesthetic agent conveniently placed, thereby carrying to the bottom of the pocket on the point of the instrument a minum of the drug each time it is inserted.

Of course teeth which are loose must, in the way deemed best by the operator, be fixed in their positions—bad occlusions corrected by disarticulation, and the teeth placed at rest; for it is difficult to estimate the nervous strain this defect alone produces.

There are many ways of fixing the teeth. The means most frequently used are silk ligatures, united bands, united crowns, and spring splints. The latter, which in many instances have given great satisfaction, are constructed by swaging a piece of gold plate to the lingual and buccal or palatal and labial surfaces, according to the location of the affected teeth, and subsequently uniting these plates with platino-iridium or clasp-metal spring wire, which when snapped over both sides of the teeth is a most excellent method of securing them, and affording easy removal for cleansing. The wire or spring is of course passed from one plate to the other between the mesio-distal-occlusal surfaces.

When some of the teeth are missing, the remaining loose teeth can be made most serviceable by bridges. All roots of molar teeth not attached to their alveoli should be amputated, for the remaining roots, properly treated, can be made to do valuable service for years in the support of crowns and bridges, and where bridges are necessary, they of course make the best possible stays or splints. The cusps of these crown abutments, however, as well as the intervening crowns, should be short or flat, in order to lessen the strain on the delicate roots which always occurs when the cusps are long or high. The bands of these crowns should never be allowed to extend under the gums, for constant local irritation will cause a return of the trouble at these points.

It has been my custom for years to put on bridges that can be removed without difficulty. This is done by lining the crowns and covering the pins with a chloroform solution of gutta-percha or Evans' gutta-percha cement, and as the chloroform evaporates, the crowns will fit closely on the prepared wet stumps. This accomplished, the gutta-percha is dried with alcohol, and the bridge is set with cement as though no lining had been used. I prefer Evans' gutta-percha cement, however, because it melts more easily upon heating than does gutta-percha, should the removal of the bridge ever be necessary.

I do not hesitate to remove the pulp from any of the teeth greatly affected, and where there is enough bone remaining to justify an effort to save the tooth. I have rarely known a case that was not benefited and the usefulness of the tooth prolonged by the extirpation of the pulp. Just why this is I do not know, neither do I know of anyone who does. It may be due to some change in the blood supply to the locality, for among teeth involved to that extent, few contain normal pulps.

After a thorough removal of all deposits, the pockets are washed with warm water. This is followed by injecting very gently a drop or two of pure lactic acid, to which have been added four drops of formalin to the ounce. As both the acid and the formalin are somewhat painful in their action, being rather escharotic, the shallow pockets are usually swabbed out with a little cotton wrapped on the point of such an instrument as a broken Donaldson broach, thus keeping so much of the acid from coming in contact with the mucous membrane. Just here I wish to say that there is nothing better for detecting any remaining deposits, however small, than this little cotton-covered instrument.

Before applying the acid, however, the lips—indeed a considerable area about the mouth—should be smeared with a little oleostearate of zinc—now called emoleo—to prevent the acid from burning, for should it come in contact with the lips or chin it is almost sure to produce what the patient calls “a fever blister” or “cold sore”—although we of course know it to be an eschar.

When the syringe is used, rolls of bibulous paper should be so placed about the pockets as to absorb the surplus acid. I have found nothing better for neutralizing the effect of the acid on the mucous surfaces, or more soothing to the membrane, than to rinse the mouth with milk of magnesia.

These precautionary measures are worth while, for the subsequent suffering is such as to make it a duty to prevent all that is avoidable.

Lactic acid was suggested to the pro-

fession for the treatment of this disease a number of years ago by Dr. W. J. Younger. This, combined with a few drops of formalin, as I have suggested, gives me results that I have not been able to obtain from any other agent. However, when the roots are sensitive, I have for many years applied zinc chlorid or a saturated solution of silver lactate, with most satisfactory results. The silver lactate has much the effect of the nitrate, without apparently causing so much or so dark a discoloration.

After the surgical and medicinal treatment the pockets are not disturbed for a week or ten days, but the official tincture of iodine is applied to the gum about every other day, and the patient directed to use some antiseptic mouth-wash half a dozen times daily. Should the pockets then show no sign of healing, it is perfectly certain that there is something remaining in them which should be removed, either a scale of deposit or some foreign substance which has lodged and acts as an irritant, and which demands that the surgical treatment be repeated from time to time until healing occurs.

It is my practice to keep under my observation each case until the recovery is manifest, for in no other way can the wound be kept clean from irritating agents, such as particles of food, etc. I consider it quite as necessary that the dental surgeon should look after his cases of pyorrhea after the operation as it is for the general surgeon to see his cases after major interventions. As the latter's cases need dressing, just so do our cases of pyorrhea need attention. Absolute cleanliness is necessary. As nothing so delays a cure or causes a return of the disease as filth, I show my patients how to clean their teeth, and insist on their doing so with a good stiff brush, for three minutes, not less than five times a day: on arising in the morning, after each meal, and just before retiring.

Massaging the gums with the fingers is always of the greatest benefit, and I demand that this be done frequently, and as thoroughly as possible. Let me say that on the dismissal of the case I always urge an occasional visit, and the hygiene

FIG. 1.

Case I. Left side before treatment.

FIG. 3.

Case I. Right side after treatment.

FIG. 4.

Case I. Left side after treatment.

of the mouth may be looked after and irritations relieved, to prevent any recurring inflammation; for should the patients again become indifferent to their general condition, and careless as to the care of their mouth and teeth, the osteoclasts will resume business.

As to constitutional treatment, much more depends upon the manner of living than upon the administration of drugs. To quote Dr. C. N. Peirce, "When I have gotten my patient to drinking water, I think I have accomplished much toward a cure of this dreaded gum disease;" so one of my most urgent injunctions is to flush the sewers, take an internal bath.

The customary diet of white bread, red meats, starches, sweets, etc., is changed for one of coarse breads—made of pure graham flour and country corn meal—nuts, fruits, and vegetables, with the caution against overeating.

The importance of deep breathing, exercise in the open air, and well-ventilated sleeping apartments is insisted upon. In other words, the patients are impressed with the importance of wholesome living, and made to feel that conditions must be changed, and that their co-operation is a necessary factor to the success of the treatment.

Occasionally one of the tonics or alkaline agents is prescribed, with more or less favorable results. In cases of a torpid liver, calomel is often a valuable agent. My general practice of late years, however, has been to put as few drugs as possible into my patients' stomachs.

CASE I.

Figs. 1 and 2. These casts represent the mouth of a lady fifty-seven years of age, anemic and rheumatic, who had for years lived principally on meats and sweets, white bread, pastries, etc. It practically shows the case as it fell into my hands, wearing an old celluloid plate to fill the spaces caused by the loss of teeth, except in the case of the crowns of the upper right first bicuspid and upper

right second molar, upper left second bicuspid and upper left third molar, and lower bicuspids, the roots of these teeth having been prepared to receive artificial crowns, and side bridges were made before saving the cast was thought of. As you see from the illustration, it is a pronounced and serious case of pyorrhea alveolaris; the gums are greatly swollen and pus is oozing from the socket of every tooth; all the teeth are very loose, save the lower bicuspids and upper left second bicuspid; the alveolar septa between the upper right second and third molars is entirely gone; also from the mesial surfaces of the upper left third and lower third molars the instrument could be easily passed to the curves of the apical ends of the roots. There was a great waste of process around both the upper canines and lower incisors, as can be readily seen in the accompanying illustration; indeed the upper canines were so loose that the cusps could be brought about half an inch nearer to each other with the thumb and finger; besides, the right canine was the seat of a chronic abscess, discharging at the margin of the gum. This tract was thoroughly scraped, also the apical end, the canal was filled in my usual way, and the pyorrhea treated as heretofore described. The crown was disarticulated, which, in a measure, put the tooth at rest.

The molars and bicuspids were cut off, one side at a time, which put those roots at rest.

Notice that after the upper left third molar was prepared for the band, it was much lower than the summit of the ridge. I hesitated before undertaking the treatment of this tooth, so great was the waste of process and so loose was the tooth. The lower incisors were ligated with silk thread for four months, at the end of which time they had become tight and comfortable. The side bridges having been made one at a time, thereby preserving the natural bite, the bridge to supply the lost upper incisors and bone under the lip was now made. For this purpose you will see from Figs. 3 and 4 that a two-incisor gum section for vul-

canite work was made use of, and answered the purpose admirably. This last bridge, however, was locked to the side bridges by lugs put into the crowns or the gold grinding surfaces of the bicuspid, thereby making a continuous bridge of the entire upper jaw except the right third molar. The lower bridges were made of the "saddle-back" teeth, except the crowns of the third molars, which of course were supplied with the usual gold shell crowns.

Six months were consumed in the treatment of this case, soon after which time the patient had gained twenty-seven pounds. She had regained her former agility of step, the roses had returned to her cheeks, and she looked to be thirty-seven instead of fifty-seven. This was eight years ago. I saw her recently, and can assure you that her mouth is in a thoroughly healthy condition. Needless to state that the diet and her entire habit of living were changed in the course of treatment, and that no drugs were given internally. Figs. 3 and 4 show the case as I dismissed it, and as it is today.

CASE II.

Figs. 5 and 6 show the casts of the mouth of a maiden lady forty-seven years of age, suffering from one of the most serious cases of pyorrhea I have ever seen. Every tooth was loose save the lower right third molar. She also suffered from torpidity of the liver, constipation, intestinal indigestion to a rather unusual degree, and was a typical case of uric acid diathesis. Before the impressions were taken, that I might not remove some of the teeth with the impression, an old upper bridge anchored to the upper right second bicuspid and first molar was removed, the bicuspid root coming away with the bridge. Finding no attachment, distally and lingually, of the lower left bicuspid, the crowns were cut off at their necks, disarticulating and putting them at rest; the pulps were extirpated and the canals filled. The lower left second molar was split with a dentate fissure bur, and on removing the distal root, no

bone whatever was found on the distal side of the remaining mesial root, or the mesial surface of the mesial root of the third molar, nor was there any process to be found on the disto-buccal and lingual sides of the lower right second bicuspid, or the mesial surface of the mesial root of the lower right first molar. The roots of the upper right molar, which had held the bridge, were resting in about a quarter of an inch of bone, and consequently the bifurcations were greatly exposed, both mesially and buccally, allowing the instrument to pass readily in both directions. The buccal plate of the alveolar process over the roots of the upper left first molar was entirely gone, and naturally the buccal bifurcation, as well as the buccal surface of the buccal roots, was wholly exposed.

I extracted in this case the upper right lateral, the lower left central and lateral incisors, and the canine, as each of these teeth, by reason of its slight attachment, would have dropped out at the least provocation. As I progressed in my study of the case, I found I could not use the lower right third molar, and though it was the only firm tooth in the mouth it was extracted.

After removing the pulp from the lower left third molar—a procedure which in connection with bridge work I always follow—and filling the canal of the remaining root of the second molar, gold crowns were made, gold caps being made for the bicuspid and lower right central and lateral, using no pins. Thus a bridge was constructed for the entire left side of the mandible, extending to the lower right canine, using the saddle-back teeth for the bicuspid and for the molar dummy. Of course the lower right canine, bicuspid, and molars, and the upper left teeth were artistically treated before the impression for the bridge was taken.

The upper right first molar roots having now become quite firm, the bridge was made, and anchored to these roots, to the canine, and to the central of the same side, as shown in Figs. 7 and 8. It is not necessary to say that quantities of pus flowed from under the gum, and that it

was in no way an encouraging case. It was treated as set forth in my paper, and the fifth month the case presented the appearance seen in Figs. 7 and 8, with not

pounds. About six years have elapsed since the treatment of this case was terminated. I saw the case again, however, about two months ago, and both the mouth and the general health seemed to be perfect.

dropped out, as well as the upper right bicuspid and first molar. So loose were the teeth of the lower jaw that no attempt

treatment and general directions as to living had been given, the patient was sent to the mountains for two months.

On her return, I was delighted to find the root of the second molar was by this time wholly unattached, and the distal

FIG. 15.

Case IV. Right side after treatment.

FIG. 16.

Case IV. Left side after treatment.

mouth astonishingly tight, except the upper right second and third molars, which were still very loose. The mesio-buccal

root was attached only on the lingual side, the attachment fortunately extending to and including the apex of the root.

As clearly shown by Figs. 11 and 12, the mesio-buccal and distal surfaces were entirely exposed, save the apex itself. After filling the canals of the roots the mesial root was amputated at the bifurcation, and though the distal root was greatly exposed, the two remaining roots of this molar, as well as those of the third molar—which was greatly involved, with practically no bone left on the mesial surface—very soon became sufficiently tight to justify bridging along with the canine and lateral. For the left side of the maxilla a bridge was made, anchored to the lateral incisor, canine, and second bicuspid roots, with a porcelain-faced dummy molar extension, the mesial half of the occlusal surface striking the distal half of the gold crown below, this crown being united to a gold crown on the first bicuspid, the second bicuspid having been lost early in life. On the right side of the mandible was constructed a small gold bridge of three teeth, uniting the second bicuspid and second molar to a small gold dummy filling the space of the extracted first molar.

Referring to Figs. 11 and 12, it will be seen that these gold bands were made very short, so as not to cover the bifurcations of the roots of the molars; for after the gums had regained their health there was an unusual exposure of all the roots in the entire lower jaw.

Having artistically treated the lower anterior teeth and the two upper centrals, the case was dismissed. In two or three months the patient was greatly restored in health, and had gained twenty-five pounds in weight. This was four years ago, and when last seen, about eighteen months ago, the mouth was in excellent condition, the teeth much tightened, and there was no redness of the gums whatever.

CASE IV.

Figs. 13 and 14. This case shows great loss in the number of teeth, as well as considerable loss of the alveolar process, especially in the left side of the upper and lower jaws. The upper right first and third molars, the lower right second

molar and first bicuspid were very loose. These teeth were disarticulated, except the bicuspid, and as no attachment was found of the palatal root of the upper right first molar and the distal root of the lower second molar, the teeth were split, and the roots were removed before an impression was taken. The left third molars were also loose; indeed, she had been advised to have all the remaining posterior teeth extracted and plates made to carry the artificial substitutes. The lower six anterior teeth were found loose, the central incisors being almost ready to fall from their sockets. These were immediately disarticulated, and after the surgical and therapeutic treatment began to tighten. The mesial root of the lower right second molar, I think, was the most hopeless case I have ever saved. There was absolutely no attachment whatever, except on the mesial surface, and as it had leaned forward so much it appeared as though lying on its belly, thereby allowing an instrument to pass over the end of the root without the least resistance.

Soon after the removal of the distal root, however, it straightened up in its position astonishingly, after a time becoming quite firm, and joined the bicuspid in supporting a very substantial bridge, opposing the bridge of the upper jaw supported by the canine, buccal roots of the first molar, and the third molar, as clearly seen at Figs. 15 and 16. The upper front teeth were in comparative health though loose, and there was practically no waste of the alveoli. There was some waste on the mesial surface of the upper left third molar. The lower left molar was very different, there being much waste of bone, involving both the mesial and lingual sides and extending almost to the end of the mesial root. The root-canals of these molars having been filled, as well as those of the canines, unusually long bridges were made to restore the extensive loss, as may be seen in Figs. 15 and 16.

The patient is a lady about forty-eight years of age, who had suffered for a long time from indigestion and rheumatism and was in a low state of health. She fell into my hands about two years ago.

After a year, more or less, of irregular treatment, we reached the condition shown in Figs. 15 and 16. I have seen her a number of times within the past

year, and upon the occasion of each visit I am forced to stand a good round scolding—not for her good health, but on account of an increase in weight of thirty-five pounds.

Fig. 19 shows one of those splints referred to in my paper, which was worn in the early part of 1897 for six months to support two upper centrals. Those two teeth are now in excellent condition.

**REPORT OF A CASE OF EXTENSIVE INJURY TO THE BONES OF
THE FACE, AND OF A CASE OF POST-TYPHOID OSTEO-
MYELITIS OF THE MANDIBLE.**

By P. FIASCHI, M.D., D.D.S., New York, N. Y.

(Read at the meeting of the First District Dental Society of the State of New York,
March 18, 1906.)

CASE I. The history of this case briefly is as follows: E. K., age thirty-five years, elevator machinist, was admitted to the service of Dr. Francis Markoe at the New York Hospital, November 8, 1902. It appears that while repairing an elevator in a building in the downtown section of the city, through some misunderstanding of the directions given to the elevator operator, the patient, who had his head and part of his shoulders projecting through a small window in the wall of the elevator shaft—past which the counterbalance, weighing 1500 lbs., ascended and descended—was struck by the descending counterbalance in the occipital region as he was looking downward. His head was carried downward and forcibly compressed against the brick wall of the shaft, in a space which certainly did not correspond with the occipito-mental diameter. He was held with his head pinned in by the counterbalance for about a space of twenty seconds as it came to a stop just below the level of the window when the elevator had stopped at one of the floors. The elevator going down, and the counterbalance going up, allowed the head to be released and the shoulders to be carried backward out through the small window.

On admission, examination showed the whole front of the face below the nasal process of the frontal bone down to the lower border of the mandible to be crushed, lacerated, and displaced backward for a distance of one inch. Both malar bones and both nasal bones were movable and were crushed backward; the

maxillæ were movable on the adjacent bones and on each other; and in addition there was a fracture of the hard palate, passing backward from the anterior teeth slightly to the left of the median line, including a fracture of the horizontal plates of the palate bones. The left maxilla was displaced downward five eighths of an inch; the left lower orbital ridge was broken and entirely loose. The patient also presented a compound fracture of the external angular process of the left frontal bone, and a compound fracture of the mandible between the right central and lateral incisors. There was a lacerated wound extending from the inner canthus of the left eye outward, about one and one-quarter inches in length, and the left eyeball sagged downward three-quarters of an inch, besides a lacerated wound of the upper lip through which two fingers could be passed into the mouth.

The left ala of the nose was torn free from the cheek; there were also lacerated wounds of the supra-orbital region and lower lip. The upper right central and lateral incisors and the two lower central incisors were missing. There was also bleeding from both ears, pointing to a fracture of the base of the cranium, and numerous contusions were noted over the back of the head and neck.

There was no paralysis; the pulse was slow and full, and the patient unable to articulate; there was considerable hemorrhage, and the man was in profound shock.

An operation was performed by Dr. Markoe shortly after admission. The face was washed, the left posterior nares

was plugged, and traction was made thereon to draw the bones forward. The wound under the left eye drained into the nares. The mouth, nares, and eyes were thoroughly irrigated with salt solution, and some fragments of the ethmoid bone were removed from inside the nose. A rubber tube wound around with plain

the hospital November 26, 1902, in an improved condition. The double-arch splint was worn for three and a half weeks, when good consolidation of all the bones except of the fragments of the mandible had occurred. A cap splint was made and cemented on to the mandible. He wore this splint for four weeks

FIG. 1.

FIG. 2.

gauze was placed in each nostril and dry dressings were applied.

The patient was seen not long afterward, and on account of the pain, the extent of his injuries, and his poor condition, he was put under chloroform anesthesia, in order that the cheeks might be widely retracted and impressions be taken of the upper and lower jaws. From these impressions casts were obtained, and a rubber splint was made *secundum artem*, bringing the bite close together and embracing the teeth of both jaws. This was adjusted the following day and a traction apparatus passing around the vertex and chin was applied so as to draw the fractured bones well up in place, especially the prolapsed left maxilla.

He was delirious, off and on, for a few days following the accident, but left

longer, during which time a solid bony union had formed and articulation was restored.

On account of the fracture of the hard palate, a spicule of bone sloughed out of the line of fracture, from about the center of that line, between the fourth and fifth week after the injury. This loss of osseous substance left an elliptic communication between the left nasal fossa and the mouth, which channel is now about five-eighths of an inch anteroposteriorly and almost a quarter of an inch across its widest diameter. To cover this defect a rubber plate was made, which he has since continued to wear.

Fig. 1 is a photograph of the patient taken some time before the accident, and Fig. 2 is another taken five months after it.

Dr. John S. Marshall, in his well-known monograph, has collected nineteen cases of fracture of the maxillæ and upper bones of the face, from the literature on the subject and from his own observation. He estimates that twenty-five per cent. of all recorded cases of fracture of the upper bones would come under this class of injury. Almost every one of the cases of fracture of the maxillæ I have seen in this city were received in elevator accidents.

I am indebted to Dr. Markoe for the data which have made possible the preparation of this report.

POST-TYPHOID OSTEOMYELITIS OF THE MANDIBLE.

Case II. The mandible is rarely involved in the bone lesions which may follow typhoid fever, as compared with the frequency in which the long pipe bones—such as the tibia, femur, ulna, and humerus—and the ribs are attacked. This may be readily seen in looking over the cases collected by Dr. W. W. Keen¹ of Philadelphia, as in the total number of cases collected by him (216) there are only two reported in which the mandible was affected; and furthermore, in the very large number of cases of typhoid fever carefully observed at the Johns Hopkins Hospital, in Baltimore, there is no mention, in the studies of Parsons² on post-typhoid bone lesions, of a case in which the mandible was involved.

The following case illustrates the pathologic condition under discussion:

D. G., age nine and one-half years, was admitted to the service of Dr. Frank Hartley at the New York Hospital, June 9, 1905, with the following history: He had enjoyed good health until March 1905, when he was taken ill with pneumonia, followed April 25, 1905, by typhoid fever. During the third or fourth week of the attack he began to experience pain in the posterior part of the left side of the mandible, between the last molar and the angle, which was followed by some swelling of the face externally over the site of the angle; this, however, soon diminished. The parents state that he

had no pain or trouble at this time with any of the posterior teeth. The physician, thinking that the trouble was of dental origin, had the last molar on the left side extracted, and then opened into a swollen area behind this tooth, from which a discharge of pus soon followed. A few days afterward the boy himself removed a portion of dead bone of about the size of a nickel from the suppurating cavity; after that the pain diminished, but the swelling increased.

A general examination of the patient showed a fairly well-nourished but rather anemic small boy; heart and lungs normal. The angle of the left side of the mandible was markedly swollen and slightly tender, and the mouth could be opened only about one inch. There is a tooth missing from the socket of the last molar, and considerable discharge of thick pus from a sinus located behind that tooth. A probe introduced into the sinus touched bare and roughened bone.

An operation was performed by Dr. Hartley, June 12, 1906. With the jaws widely separated by a suitable mouth-gag, the first molar on the left side of the mandible was extracted, and a number of necrotic pieces of bone were removed from the horizontal and descending rami, the cavity being thoroughly curetted and packed with iodoform gauze. An area of about one and one-eighth inches of the lower end of the descending ramus and of the posterior part of the horizontal ramus and angle was thus removed. On account of the removal of this amount of bone, the jaw naturally deviated at once to the left. To overcome this, a retaining appliance of rubber similar to a double-arch interdental splint was subsequently made, to hold the mandible in correct articulation with the maxilla and to secure a close bite.

The patient left the hospital June 24, 1906. Since then he has worn the retaining appliance for three and a half or four months about as diligently as this class of hospital cases may be expected to do; at that time he stopped wearing it, as he found that he had a good articulation and could use the mandible freely. On the following October the area re-

FIG. 3.

moved from the mandible was found to have been completely regenerated, and was firm and solid. The deviation of the median line of the mandible from that of the maxilla amounts to about one-half the width of the lower central incisor, whereas immediately after the operation it was almost three-quarters of an inch. An X-ray plate (Fig. 3) taken at this time shows the area of regenerated bone very plainly, and also a faint line across the descending ramus, where apparently calcification has not yet become complete. The interior of the mouth is healthy with the exception that the bone at the angle does not on bimanual palpation feel as thick as on the right side, there being in appearance no difference between the two sides. Bacteriologic ex-

amination for the bacillus of Eberth was negative.

I would call your attention to the exceedingly fine result Dr. Hartley has obtained in operating on the case from within the mouth, whereas in hospitals, cases of this class are generally treated by incision and scraping from the outside.

This is the second case of this kind following typhoid that I have seen; the other, which I observed some two years ago, involved the symphysis, but not the whole depth of the bone at that point.

FORCING ERUPTION: A CASE IN PRACTICE.

By H. HERBERT JOHNSON, D.D.S., Macon, Ga.

(Read before Section II of the National Dental Association, Atlanta, Ga., September 18, 1906.)

IT having occurred to me that there might be enough features of novelty connected with the management of this little case to bring out some points in the treatment of irregularity, I have decided to present it in this short illustrated account. The case consists of one of these slight complications of dentition, often produced by the disobedient neglect of patients. This young lady, having no other immediate trouble to force her to pay the usual visit to the dentist, neglected to come until the fifteenth year, when she made a visit for examination and advice.

On examination I found both deciduous canines in place and quite firm, and the most searching examination I could make did not reveal to a possible certainty the position or even presence of the permanent canines. Knowing that some day, perhaps right in the midst of

her young womanhood, these deciduous teeth would loosen and come out, I thought best to extract them at once. Before doing so, however, I decided to inform myself absolutely of the position and presence of the permanent teeth. I therefore had her go to Dr. Thos. P. Hinman, who very kindly made for me some beautifully plain skiagraph views, one of each side of the mouth.

The presence and position of the teeth were now perfectly revealed. The one on the right side was pointing straight for its position, and it was very evident that no trouble would be experienced with that one, as is shown in the skiagraph reproduced in Fig. 1. The one on the left, however, was not in the least assuring. This tooth was lying very flat on the palatal side of the ridge, its crown resting opposite the apex of the lateral incisor, and the end of the root

resting nearly opposite the apex of the first bicuspid, as will be seen by reference to the skiagraph, Fig. 2.

ence to Fig. 4 the conditions will be seen as they existed after waiting one year, when the permanent canine on the right

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4

The condition of the mouth immediately after extracting the deciduous canines is shown in Fig. 3, and by refer-

ence to Fig. 4 the conditions will be seen as they existed after waiting one year, when the permanent canine on the right

cut through and open up the tissues and force it down. I began by making a circular incision of about a half-inch in diameter directly over the crown, taking out a plug of gum tissue, and using the skiagraph as a guide. I then chiseled

platinum hook for fastening a rubber band.

The little appliance shown at Fig. 5 was then made and cemented into place on the first bicuspid and lateral incisor, making a kind of bar or bridge with a

FIG. 5.

FIG. 6.

away a thin plate of bone exposed by removing the gum tissue, and came directly to the crown of the tooth. The opening was then packed for a few days until the hemorrhage could be checked, when a small hole was drilled into the surface of the crown which presented upward—which when the tooth was righted became the disto-approximal surface. Into this hole was cemented a small iridio-

hook in the center, from which a rubber band could be stretched to the hook in the tooth. The result was entirely satisfactory. The tooth came down as promptly as it would have been safe for it to do, or as fast as it would have been possible, to avoid destroying the pulp. After getting it well down with the pulling appliance, the position of which may be seen by reference to Fig.

6, a rest was taken to allow nature to adjust matters awhile. in Figs. 7 and 8. The principal difficulty encountered was in keeping the wound

FIG. 7.

FIG. 8.

By means of a jackscrew, extending from and attached to the opposite bicuspids and molars, it was then pushed into its proper position in the arch, as is seen

from healing and closing up the opening, thus making it troublesome to adjust the little rubber bands, which had to be renewed quite often.

THE BANDED *VERSUS* THE BANDLESS CROWN.

By SAMUEL DOSKOW, D.D.S., White Haven, Pa.

(Read before the Luzerne and Lackawanna Dental Society, at Wilkes-Barre, Pa.,
May 15, 1906.)

THE subject of root-crowning has attracted the attention of the profession from its earliest history, resulting in a multiplicity of methods and conflict of opinions too numerous to mention. That inherent human characteristic—the individual's belief in his particular way—is a condition that always has obtained and probably always will. The spirit of this persistence is regrettable as a factor in impeding progress and lowering the dignity of discourse. One truth, however, is made apparent by this crown controversy, in that, in this conflict of opinions, the absence of a scientific standard of measurement is still clearly apparent. The monthly review of methods or modifications of details all show a dickering with a superstructure based upon the original principle—which is probably wrong, and therefore susceptible of indifferent refinement.

Beginning with the pivot teeth of Fauchard and Dubois de Chemant, the wooden pivot teeth, and the crowns of Richmond, Bonwill, Logan, Downey, and Davis, we can trace distinct phases in development. The apparent faults of one were overcome in the other, and so on down the whole line, each according to his ingenuity and skill in production.

While some general methods were thus evolved that are applicable in a majority of cases, yet strictly speaking, no one method in vogue is applicable in every case, either because of some fault in the principle underlying it, or through the lack of ability in the average practitioner to produce that which nothing but the highest skill is capable of accomplishing. It is readily seen, therefore, that

something different from the methods practiced at present is needed, in order that one method applied with the average skill may answer for every case.

It is interesting to note the different attitudes taken by the leading dentists in regard to this subject, the more so since the entire profession is divided into different camps on this point in particular, consciously or unconsciously following the lead of one or the other. For instance, Dr. Walter H. Neal (*Dental Brief*, October 1901) makes a radical and thorough sweeping statement against the use of the band around the root in the making of crowns. His denunciation of this method is so sharp and bitter that in no place could he find any use for it. Much in the same line, but not so poignant a criticism, comes from Dr. H. C. Register (*International Dental Journal*, February 1902) who says that there are many, if not more, roots destroyed by this method of crowning than are saved by it, because of the production of irritation which induces gingivitis, leading to pericementitis and other ills that follow irritation of the pericementum, and that the band should be used with extreme care and only in exceptional cases. Dr. Joseph Head (*DENTAL COSMOS*, July 1904) finds cause from quite another standpoint for advising against the use of bands. He claims, and in this he has my hearty approval, that theoretically it is possible to fit a band around a root and make it perfectly smooth with the contour of the root, but is that the case in practice? And if in practice it is not possible, then every band is a source of infection. Nevertheless, in the cases of

split roots, he admits that it fills a want that can hardly be filled by any other device.

On the other hand, Dr. Hart J. Goslee (DENTAL COSMOS, January 1901) writes: "As the result of experience a great majority of the profession now agree that a crown with a band encompassing the end of the root is essential to permanence, because of the immunity from the penetration of secretions into the joint, the protection to the root from subsequent decay or fracture thus afforded, and the increased stability. Hence it seems needless to more than mention with emphasis that a perfect-fitting band is the first essential."

Dr. F. H. Metcalf (*Pacific Dental Gazette*) while favoring the bandless crown, yet holds that for strength and durability the banded crown still leads, and claims that with the careful operator it is to be preferred in all cases. And from what I can recall of the teachings of Dr. F. A. Peeso, I gather that every root that is worth crowning at all should have a band around it.

From the data thus quoted, it is no wonder that not only the novice, but the average practitioner, is so bewildered that he does not know the exact course to pursue and is, as stated above, a follower of one camp or another. And yet both are not far from the truth, for if they were, the results obtained by both methods would be far from being as favorable as they really are. For in spite of all the objections to the banded crown, there are probably thousands of cases in which, although the band was employed indiscriminately, everything else having been equal, satisfactory results have followed its use. And on the other hand, especially within the last decade, just as large a number of manufactured crowns have been inserted, that have, from all reports, proved to be likewise satisfactory.

It would therefore be in place to consider the merits and demerits of the various crowns now in use, and to deduce from them a method that would possess all the requirements, viz, strength, durability, esthetic qualifications, ease of construction, and applicability to all cases.

To this end I shall refer to all the porcelain crowns on the market under the name of manufactured crowns, as there is not much difference between them, and also because they are familiar to all.

As above stated, the chief claim in favor of the banded crown is that it is more reliable and has a wider range of application. Let us now pass in review the open objections to this form of crown:

First: The proper mechanical fitting of a band around any shaped body is only possible where the sides of that body are parallel, or as in the case of a cone, where the fitting is done by forcing the band from the point toward the base. Neither of these conditions holds true in the case of a root. In the fitting of a band around the root in the mouth we have to do with the base of a cone, and the higher the band is carried along the root, the poorer is the fit.

Second: Even if a proper fit were practicable it would be impossible to tell when the band impinges upon the peridental membrane, causing irritation, resulting in pericementitis and the subsequent ills that may follow this disturbance.

Third: The thickness and width of the band that is usually employed, in order that it may effectively produce the results claimed for and demanded of it, are far in excess of the amount of tissue removed by the cleaving away of the enamel, thus necessarily acting as an irritant upon the gum. It is nothing uncommon to find that part of the gum immediately overlying the band congested, purplish blue, and puffy, in those cases where no appreciable recession has taken place, or else the gum so receded as to expose the free edge of the band.

Fourth: The floor of the cap can seldom be formed perfectly flat for the proper fitting of a facing against it, and in order to preserve its surface from checking during soldering. In forcing the post through the floor of the cap preparatory to soldering, a shallow depression is invariably formed that could be, but usually is not, covered by the ordinary method of backing. This depression forms a handy pocket for the trickling

down of borax, and is the cause of many checked and cracked facings.

In view of all these objections, it would seem advisable that the profession set to work to evolve a different method. On the other hand, we are supplied through the agency of the manufacturer with porcelain crowns under various names, but which in reality differ very little or not at all in principle. Let us look into the vulnerable points of these crowns:

(1) Bearing in mind the motto laid down by the late Professor Harris that "the base of the crown should touch every part of the extremity of the root," we are at once confronted by a serious objection to this form of crown. How many of us can say, in every case where a manufactured crown was employed, that absolute contact at all points of both surfaces was obtained.

(2) Granting for the sake of argument that perfect adaptation of the crown to the root is possible, its retention is not thereby strengthened. As is to be expected, the line of cement between crown and root is very thin—indeed, theoretically it is only of microscopic thickness—and soon dissolves out, thus providing a suitable and inviting space for the invasion of micro-organisms. Even if it should chance that the reaction of the secretions of the mouth is such that it will not have any deteriorating effect on the cement, no strength is added to the retention of the crown, for according to the experiments of Dr. Joseph Head (see DENTAL COSMOS, July 1905), the strength of cement is dependent upon its bulk.

(3) The pin and tooth united is as a lever. The fulcrum is the fixed base over which the lever works, resulting either in the splitting of the root if the pin be made of a stiff material such as German silver, or in the bending of the pin and the forcing of the crown labially, placing it out of alignment, if the pin be made of a soft material such as platinum. In addition a suitable pocket is formed for the lodgment of food débris, followed by the inevitable destruction of the root.

(4) The number of molds is not suffi-

cient to fit every case. All the crowns manufactured are made from standard—or what is adopted by the manufacturers as standard—molds. Very seldom can a crown be found to suit the case in hand. Time and again do we come across crowns—intended to replace missing incisors—that will be wider than the root mesio-distally and narrower labio-lingually, or *vice versa*; while as regards the appearance, nothing better could be desired.

(5) In cases of close bite, or where the natural teeth are very thin labio-palatally, it becomes necessary, in order to comply with the requirements of the bite, to grind away the crown on the palatal surface. The crown is thereby weakened in proportion to the thinness of the porcelain overlying the part of the pin embedded in its body—either baked or cemented in. The breaking of a majority of crowns could be traced to this cause.

(6) The disregard of the anatomical characteristics of the root and of the mechanical value of the pin is shown in those instances when the patient appears with the crown in his hand and the pin in the root. This is a frequent occurrence with the crown that has a threaded pin, which is screwed into the crown and fastened by cement. It usually breaks even, if the last thread is on a line with the cervical surface of the crown.

(7) The applicability of manufactured crowns is limited to sound roots, where the decay has not extended beyond the gingival margin. It is needless to say that the conservative dentist meets with very few cases that present this favorable condition, for wherever they are encountered the tooth could probably be saved without resorting to crowning.

(8) Although some attempt has been made by the manufacturers to furnish substitutes for teeth placed irregularly in the arch, and especially those cases of overlapping central and lateral incisors, we can safely say that they have not only fallen short of the mark, but have not even approached it sufficiently near to be entitled to the claim of an imitation. Those who have made an extensive use of these crowns will admit the total helplessness of such cases.

(9) Last, but not least, the slovenly effect upon dentists. The number of crowns met with in the mouths of patients where they extend beyond the periphery of the roots and act as irritants upon the gums, and the reverse case, where the roots extend beyond the margins of the crowns and thus are exposed to the action of micro-organisms, is so large that it is of sufficient cause to warrant the abandonment of their use.

In the spirit of compromise to the objections to both the Richmond and the manufactured porcelain crowns, another known as the "half-cap crown" was introduced by Prof. W. F. Litch and recently revived by Dr. R. M. Sanger (*DENTAL COSMOS*, August 1903). The advantages claimed for this form of crown are that it overcomes the chief objection to the Richmond, viz, the unsightliness of the exposure of the gold band in front, caused by the recession of the gum, and that it is stronger than a bandless crown in that a large part of the circumference of the root is encircled by a band. This argument is wrong both in theory and principle. The force of the bite is upward and outward, while the band covers only the palatal and parts of the approximal walls, thus not offering any resistance to the force of the bite. A common result is that with the continued force of the bite it is forced outward, carrying with it the band, and forming, as in the bandless crown, a favorable place for the development of caries.

Another claim made in its favor is that the band of enamel surrounding the root under the gum adds sufficient strength to the labial part of the root, so that a full band is uncalled for. I think that all will agree that the strength of the enamel, like that of porcelain, depends upon bulk; and that the amount left after the root is ground level with the gum is so little that it cannot be regarded as sufficiently strong to protect the root against splitting. The ease with which it yields to the cleaver is sufficient proof.

And again, even if it were sufficiently strong to fulfill all the claims made in its favor, the adjustment of a band to the palatal half of the root over the intact

enamel is a source of irritation to the gum and peridental membrane. Whether it is made according to the method advocated by Dr. Litch or according to that advocated by Dr. Sanger, it is bound to produce the same results as regards the gum and peridental membrane, and in addition forms a lump—bulky and cumbersome to the tongue—on the palatal surface, extending beyond the natural line of the teeth.

Another crown that was devised to fill the need is the Williams crown. It is made by forming a groove around the canal by means of a trephine, and fitting into it a ferrule that is furnished by the dental depots.

The fallacy of this principle is obvious. The root is materially weakened by the circular groove cut around the canal, so that instead of adding strength, which is the main requisite, the root is thereby rendered more apt to split. It is also necessary to bear in mind that roots are not round, and that it is not possible to apply a round trephine in all cases. The difficulty of applying a manufactured article to all cases in the mouth forms as valid an objection in this case as in the case of manufactured crowns.

It is with a feeling of gratitude toward its author that I have undertaken to present before you a crown devised by Dr. P. B. McCullough of Philadelphia. Although it was presented to the profession about five years ago, and has since been demonstrated before various dental conventions, I can safely say that it is still unknown to a large majority of the profession, and even were it not so, it would bear repetition because of its merit. As stated above it is a method that will answer for every case and requires no more than the average skill for its application; in this respect the McCullough, or as he terms it, "the burnished cap crown," fully comes up to the standard.

The chief features of merit in this method are that the entire work is done on a cast made from oxyphosphate cement, the strain on the nervous system of the patient and the amount of pain inflicted are reduced to a minimum, and it contains all the virtues of a band-

less crown and the advantages of a banded crown.

The root is ground down by means of carborundum stones slightly below the gum margin, following the festoon of the gum, and the remaining enamel is cleaved off. The root is then beveled with a cone bur, thereby converting it into an inverted truncated cone. (Fig. 1.) Any instrument whose strength depends upon bulk, or that has to be used as a lever to form a bevel, is contra-indicated for that purpose. In the first place, it is difficult to insert it between the approximal spaces, and in the second place, an instrument that works on a fulcrum will never produce a straight-line bevel, but

FIG. 1.

invariably one that is slightly curved. To overcome this difficulty the cone bur is used. It comes in various sizes, and is therefore easy of manipulation in all places. The approximal spaces as well as badly decayed roots that extend for some considerable distance beyond the gum margin can be reached with it and beveled, as easily as can the labial and palatal surfaces. The bleeding from the gums that usually accompanies all operations of this nature is easily checked by a stream of cold water from a syringe, which also cleans the part from the débris caused by the bur.

An impression tube, funnel-shaped, is made from a thin piece of German silver cut in the shape of a keystone, the edges of which are bent together and soldered with silver solder. By means of pliers and shears, it is made to fit loosely around the bevel and under the gums. It is then

filled with wax to within one-quarter inch of its wide surface. (Fig. 2.) Any cheap quick-setting cement is then mixed to a medium consistence, placed in the

FIG. 2.

tube, and pressed against the face and bevel of the root. The tube is held between the thumb and the first and middle fingers, the other fingers resting against the adjoining teeth or the roof of the mouth so as to keep the tube in balance.

An impression of the root and bevel thus taken, a facsimile of the root in cement is the next desired step. As a separating medium, the soaking of the impression for about ten minutes in formalin or the coating of its surface with glycerin can be employed. The glycerin works better in my hands, and is therefore always used. As the outer edge of the bevel is usually on a line with the edge of the impression tube, in order that a cast of a suitable size may be obtained, it is necessary to form a matrix around the impression. This is accomplished by holding the tube in the corner of a piece of paper about the size of a prescription blank, and rolling until it is well wrapped. A wax thread is wound around the paper tube to hold it in place. The matrix is then trimmed to within a quarter of an inch of the impression (Fig. 3), and the surface of the impression is moistened with glycerin. Any cement, such as Weston's or Climax, is mixed to a thick consistence and packed into it. It is then held under pressure between thumb and finger for about ten minutes to prevent it from warping. When the cement has set, the matrix is removed, and the cast and impression are separated by pulling them apart.

The excess cement is cut away with a coarse stone, care being taken not to grind beyond the upper edge of the bevel. For the sake of convenience in handling,

FIG. 3.

the cast is mounted on a block of plaster or wood and fastened with hard wax. (Fig. 4.)

FIG. 4.

A piece of inlay platinum of suitable size is placed over the cast, held firmly

FIG. 5.

by the thumb of the left hand, and with a large burnisher the edges are burnished down the bevel and beyond it. This forms

a fairly fitting cap to cover the end of the root. (Fig. 5.) It is now laid aside, and a strip of 22-k. gold, No. 30 gage and about one-eighth inch in width, with angular ends, is measured loosely around the outer edge of the bevel. The ends are soldered together with 22-k. solder, and the band thus formed is shaped by pressing it over the cast. In thus shaping the band, it is always necessary to bear in mind that its walls should be parallel with a line drawn vertically through the center of the cast. The band is then removed, the cap annealed, placed on the cast, and the band pressed into place

FIG. 6.

over the cap, drawing it tight over the cast. The cap and band are then removed and soldered together with 22-k. solder, freely covering the cap with solder from the surface to which the porcelain is to be attached. The overhanging edges of the platinum are then trimmed even with the outer edge of the bevel, and the outside of the band beveled toward the roots. This makes the band perfectly smooth with the contour of the root, and overcomes some of the objections to the banded crown, and in addition restores the amount of tissue removed in preparation. (Fig. 6.)

The pin is formed by filing flat at an angle a round piece of iridio-platinum wire No. 18, about two-thirds the length of the canal, and soldering its flat surface with 22-k. gold to another piece of the same thickness, about one and one-half times its length. (Fig. 7, *a*.) It is then filed flat into the shape of an obelisk. (Fig. 7, *b*.) It could also be made from two wedge-shaped pieces of clasp metal soldered together. Thus a pin is formed that will be strongest in the direction of greatest force, and will be equidistant from the periphery of the root. A hole is then punched in the center of the cap and enlarged by means of a bur to admit

one-half the length of the pin. This is done so as to prevent the turning up of the edges when the pin is forced into place.

At the next visit of the patient the cap is placed over the root and—assuming that the canal has been previously enlarged—the pin is forced through the

FIG. 7.

hole in the center of the cap into the canal as far as it will go. By slightly pulling on the cap with thumb and first finger, the cap and pin can be removed together and soldered with 22-k. solder. This is best accomplished by resting the cap over two pieces of charcoal, fire-clay, or pumice, with the pin suspended between them, or by previously drilling a hole in the asbestos block sufficiently wide and deep to admit of the free suspension of the pin without any tendency to dislodge it, the edges of the cap resting on the block.

The pin being soldered fast, and providing a hold for the fingers, the cap is held against the flat surface of the lathe stone, and the band extending beyond the cap is ground flat at the angle that will be narrowest labially and widest palatally. It can usually be ground so that labially the band will be cut away beyond the inner edge of the bevel, thus insuring the absolute covering of the gold by the gum, and overcoming another valid objection to the banded crown. (Fig. 8.) It also—in the least amount of time—forms a flat surface against which a porcelain facing can be ground to fit accurately.

The section thus completed is placed upon the root, an impression taken, casts made, and the bite taken in the

usual way. A facing of the proper mold and shade is selected and ground into place, and attached by means of hard wax. It is now removed from the cast, and lines are drawn with a sharp knife on the walls of the cap in line with the flat surface of the facing. To facilitate the removal of the cap and pin from the cast, it is well, prior to the pouring of the cast, to cover the pin with a thin layer of wax. On heating the cast

FIG. 8.

slightly prior to the attachment of the facing, the wax is softened, and the cap can be easily lifted from its place without disturbing the relationship of the facing and cap.

The next step is the formation of a backing. For this purpose 32-gage platinum is used. It is made to extend at least one-sixteenth of an inch around the free edges of the tooth, and is swaged against the facing by striking a soft wooden stick placed on the labial surface of the facing with a light horn mallet into moldine. This outlines the margins of the facing distinctly, and protects it on all the free edges against coming in contact with the flux during the process of soldering. The remaining edge of the backing is cut flush with the ground surface of the facing. For the protection of this surface, crown metal—gold on one side and platinum on the other—rolled to a thickness of 0.001 in. is used. The backing is removed from the facing, and placed on the soldering block, with the surface that comes into contact with the porcelain downward. A piece of crown metal of suitable size is placed over it about one-sixteenth inch below the upper margin of the backing, gold side downward. With the blowpipe the gold of the crown metal is made to melt, soldering the metal to the backing. It is then returned to the facing, and with the finger, the crown metal is bent over the ground surface of the facing,

the free edges extending beyond its labial surface. Another advantage gained by the addition of the crown metal is that the gold surface coming in contact with the ground surface of the facing lends to it a yellowish tinge, which at that part of the facing is very desirable. To insure against the probable leak of flux around the pins, in case the holes punched in the backing for their admittance are slightly larger than the thickness of the pins, small washers made of 36-gage pure gold and punched out with a sharp-pointed instrument are slipped over them. The washers are carefully burnished down with an instrument provided for that purpose. (Fig. 9.)

FIG. 9.

The immediately adjoining teeth in the cast are now partially cut away to allow for the extension of the edges of the backing beyond the margins of the facing. With the lines on the sides of the cap as guides, the facing is waxed into place. It is then removed from the cast and invested. When hardened, the wax is washed out with a stream of boiling water. Small pieces of solder covered with borax are placed at the points of contact of the crown metal and the cap. A few pieces of platinum or clasp metal are placed at the various points in order to draw the solder for the reproduction of the anatomical contour, over which large pieces of solder are placed. The investment is heated up in the usual way, the heat being applied to the under surface of the investment immediately beneath the joint of the facing and the cap, until the small pieces of solder placed at that point melt and flow down, when the

flame can be applied on the surface to facilitate the flow of the solder, and the covering with it of the entire surface of the backing. If these precautions are carried out, a most perfect joint between the facing and the cap will be obtained, and checking of the facing, even of microscopical character, will be avoided.

The incisal edge of the facings to be selected in this work should be of the knife-edge order. When the contour is properly restored with solder, the danger of snapping off a facing during mastication is reduced to a minimum, as the opposing teeth always come in contact with the gold first, and with no unsightly showing of gold at that point.

The excess of platinum and solder is cut away with a stone. The grinding should be done against the facing, as it tends to the production of an absolutely fine joint. It is then finished in the usual way. (Fig. 10.)

FIG. 10.

In favorable cases, or where the dentist is a porcelain enthusiast, an all-porcelain crown can be constructed on this principle. The cap is made in the way already described. A detachable-pin porcelain crown of the proper shade and mold is selected and ground flat to fit the flat surface of the cap. The detached pin is cut, the part belonging to the crown is replaced in the space provided for it in the crown, and filed flat with the base of the crown. A small piece of hard wax is placed on the pin, the cap is heated, and the crown placed on it. In a minute the crown is removed from the pin. The latter, waxed in place to the cap, is removed with it from the cast, in-

vested, and soldered. The crown is then fastened to the pin and cap with cement.

FIG. 11.

When set it is ground wherever necessary in order that it may fit flush with the cap. (Fig. 11.)

In cases of edge-to-edge bites we have observed that a porcelain crown attached to a cap will in some instances hold better than a soldered crown. A case that came to my notice about a year ago illustrated this fact plainly. Both upper central incisors were replaced with crowns by different dentists. One was a Richmond crown, and the other a porcelain crown attached to a Richmond cap. The latter did good service for about five years, while the former only lasted one year. While one case is not sufficient data for conclusive purposes, yet it is worth bearing in mind and comparing it with other cases that may be heard of from time to time.

A NEW METHOD OF OBTAINING PLASTER IMPRESSIONS IN DIFFICULT CASES.

By R. MACDONALD, D.D.S. Univ. Pa., Brisbane, Australia.

THE difficulty attending the obtaining of plaster impressions is in ordinary cases overcome by the use of perfectly fitting cups and good impression plaster; but certain cases, which come regularly, cause the most skilful operator to hesitate as to the propriety and expediency of using plaster. I refer to those patients well on in life whose teeth are extremely elongated and somewhat irregular, some of them with a slight tendency to looseness, but not sufficiently so to warrant extraction.

As to the particular material to use in these and all other cases, I presume that there can be no question as to the incomparable superiority of plaster. The well-known method of oiling the cup, drawing it away from the impression in the mouth, and then breaking up the impression into sections or pieces and replacing in the cup, is to any others than the skilful a very difficult operation, and calculated in many patients to occasion considerable discomfort and alarm. The

chance of a dislodged piece of plaster getting back into the throat and larynx, as well as the general difficulty, often induces many operators in these specially difficult cases to resort to modeling compound or other inferior impression compounds.

I have recently in my practice had occasion to construct dentures for some cases of the nature mentioned, i.e. elderly people with very elongated irregular teeth, somewhat loose, and I have adopted a method which has given such good results that I respectfully beg to lay it before the readers of the Cosmos.

First I obtain a modeling compound impression, and run a plaster cast in the ordinary way. Having obtained this cast I build on it a thick wax plate as if for a bite, but which goes only about one-quarter up the height of the teeth from their cervical portion, and with a small knife trim away the wax where it embraces the teeth, so as to leave a clear space of say one-eighth inch around

all the teeth; then with an excavator the wax plate is scratched on its interior or palatal surface, and also on the cut-out portion encircling the teeth. The object of this scratching is to allow the impression plaster to attach itself. I then mix some S. S. White impression plaster in the ordinary way, put some all over the palatal surface of this specially improvised wax cup and insert it in the mouth. Some of the plaster is forced through the cut-away spaces of the wax around the teeth. A perfect plaster impression is thus obtained of the palate, alveolar ridge, and portions of the teeth. As the wax plate only goes up one-quarter the height of the natural teeth from the cervical edge, the impression ends there. It is easily withdrawn. Indeed, extra time may be given as regards the setting of the plaster, and only the slightest fracture of the plaster takes place even in the most difficult cases. A clear sharp plaster impression is thus obtained for the basis and foundation of the work. The impression after being withdrawn from the mouth is painted in the usual way, and a cast run, the palate, alveolar ridge, and one-quarter of the teeth from the cervical margin being reproduced.

In the event of its being a gold denture, this is all that is required for the sand castings, which are duly made, and the gold plate swaged. The swaged plate is now put in the mouth, and will be seen to go unerringly to its place, owing to the great accuracy of the plaster impression. A modeling compound impression is now taken with an ordinary cup, the gold plate being in its position in the mouth, and the cast is run from this. It is then set up on the articulator and the case is finished.

In the event of the denture being vulcanite throughout, I proceed as follows: Having obtained the plaster impression in the specially improvised wax cup, the cast is run in the ordinary way; the palate and alveolar ridge are thereby reproduced with all the teeth to one-quarter of their height from the cervical margin. In other words, a cast of the mouth is reproduced, except that the teeth are reproduced only to a height of say one-

quarter of an inch from their cervical margins—they appear as if they were cut off at that height above the gum.

Instead of making a swaged gold plate, rubber is run on and vulcanized, so as to produce a solid base about two or three times the thickness of an ordinary gold plate. This vulcanized base is now tried in the mouth, and owing to the perfect plaster impression, it will be seen to go exactly to its place, to be absolutely steady, and fit closely against the teeth. The case is then treated as the gold case was, the vulcanized base is put in the mouth, and a modeling compound impression taken with an ordinary impression cup. The cast is run in the usual way, then set up in the articulator and the case finished. The taking of the modeling compound impression is only an auxiliary, and subsidiary in importance, as the basis of the work has been secured by the first impression taken in plaster.

The undercut or overhang of the natural teeth will—especially where the vulcanized base is used—be modified, owing to the presence in the mouth of the vulcanized base-plate, which rises to one-quarter the height of the teeth, thereby doing away with some of the undercut. The tendency to distortion of the modeling compound will consequently be lessened; if, however, the modeling compound does catch, as is inevitable in these irregular cases under consideration, the distortion will in no way affect the base or foundation of the plate, which has been already exactly secured by the plaster impression.

There are one or two points which may be mentioned as regards the details of the work. The vulcanized base should be roughened by cuts on its external or lingual surface from the fret saw, so as to insure the attachment of the rubber used in the second vulcanization. Another point is, that before taking the plaster impression in the specially improvised wax cup, I put three little pellets of wax on different points of the interior or palatal surface of the wax cup—i.e. on the surface which is in contact with the palate—the object being to prevent too close contact of the wax plate

to the palate. In this way I insure a certain definite thickness of impression plaster. I have found it an advantage also to strengthen the specially improvised wax cup in lower cases by putting a thin sheet of modeling compound along its external surface.

In conclusion, I would state that I have tried this method in various cases during the last three months, and it has given absolutely satisfactory results. Its chief claim is that it simplifies and makes easy the obtaining of perfect plaster impressions for the basis and foundation of the

work in the most difficult cases. The use of this method also carries out a well-known principle mentioned in the "American Text-book of Prosthetic Dentistry," namely, that "the plaster covering the vault and arch should be of uniform thickness in order to insure the best results." An operator of ordinary ability can by this method obtain the most exact results in his work, and give a comfort and satisfaction to the patient which would be denied him were he to rely on any impression material other than plaster.

A METHOD OF REPAIR THAT CAN SUCCESSFULLY BE APPLIED TO SOME CASES OF FRACTURED BRIDGE OR CROWN FACINGS.

By HERBERT H. BETHEL, A.M., D.D.S., Philadelphia, Pa.

A CASE once presented itself in my practice in which circumstances rendered it inexpedient for me to remove a piece of bridge work in order that two bicuspid facings which had broken off might be repaired. The bite was such that it would not admit of any extra metal linguo-occlusally, and the backings were so thin that I could not hope to use such a method as Zentner's riveting or Bryant's screws and nuts.

I may say here that the facings had broken out on account of too thin a backing and exposure of the facings to a very heavy bite.

Realizing that I could not employ any of the usual methods, I thought out the following, which may be in use by many, although I had not before heard of it, and a claim to originality is of less moment than the usefulness of the idea:

I trimmed the old jagged backing and bent it with pliers until I had nothing more to fear from the bite. Then I straightened the pins, and filed the little heads up, so that they were of the same gage as the pin. Of course, in cases in

which the pins in soldering have been crystallized, and snap off in the porcelain, this method cannot be employed. The pins must be intact after the remaining chips of broken facing have been cleared away.

Now prepare to bake porcelain-inlay facings. A matrix is needed. This can be burnished directly on the bridge, or a dental lac or modeling compound impression taken and the matrix burnished to the model. I can suggest but two methods to obtain the holes in the porcelain facings so as to allow the new facing to fit down over the pins:

(1) Take platinum tubing that fits accurately over the pins. Cut off little pieces a trifle longer than the pins, and pinch this trifle in the pliers while the tube is still on the pin. This closes the one end of the tube. See that the tubes, two to each tooth, come readily away from the pins. Now burnish the foil—either No. 30 gold for low-fusing or 100% platinum for high-fusing body—to the old backing and the gum, allowing the pins to puncture it. When well bur-

nished replace the little tubes, and with yellow beeswax—as hard as it can be worked—remove the matrix and tubes together. Carefully, and without disturbing the position of the tube in the wax, slip steel pins one-fourth to three-eighths of an inch in length into the tubes and pour the impression with powdered asbestos 2 parts, plaster of Paris 1 part, engaging the protruding pin ends. The pins should be selected beforehand and should accurately fit the tubes. Coat with moistened whiting the end that goes in the tube. Dry the cast gently, remove the wax by dry heat and cotton fiber, and bake on the porcelain body in such a way as to avoid drawing the tubes awry, and contour carefully at the cervix.

(2) This method is similar to the first in the general method of procedure, except that instead of platinum tubes,

gold-wire pins a little heavier than the tooth-pins are baked in the new facing. These pins of pure gold are slipped into the wax impression through the punctures in the matrix, no tubes having been used in the procedure.

The pins are long enough to be held by the investing material, and are afterward cut off and with the engine bored out of the porcelain. As the gold is so soft, this can be readily accomplished. Set the facings with cement as carefully as for an inlay, roughening the pins, backings, and back of the facing. Protect well while the cement is setting.

If the bite is judiciously handled, the work will be successful, and although the account is somewhat lengthy, the method is really a very easy one to a man accustomed to working with porcelain.

THE BLUE LIGHT AND HEAT AS THERAPEUTIC AGENTS.

By A. W. HARLAN, M.D., D.D.S., New York, N. Y.

(Read before the National Dental Association, in general session, at its tenth annual meeting, Atlanta, Ga., September 16, 1906.)

FOR several years hints as to the usefulness of the blue light have appeared in our journals and the daily papers, without much thought as to its utility as a therapeutic agent. Many years ago, from the experiments of General Alfred Pleasanton, Mr. Gladstone, Prof. John W. Draper, Schellen, Pancoast, and others, some things were learned with reference to the action of the blue light on vegetation and fruit-growing, but not much was obtained relative to its action in inducing relaxation of the nervous system as a whole. It was found that in all cases of "excessively accelerated tension," much relief was experienced when the blue ray was used.

It remained for Professor Redard to demonstrate by this means a sort of anesthesia which would enable the operator

to extract a tooth or two after an exposure of the eyes to a blue ray through an electric lamp. This was done by using a sixteen-candle lamp, with a bright metal reflector, held at about four inches from the open eyes of the patient. The head and the lamp were covered with some dark blue cloth, and the room was darkened for about two or three minutes, when the anesthesia was sufficient to prevent pain in the extraction of two or more teeth.

After reading Professor Redard's article a little more than two years ago, I had a blue lamp installed; for some reason, however, it did not act perfectly well, so I used a reflector composed of a series of mirrors, which gave me much better results.

After a time I came to the conclusion

that I could improve upon this, so I had a lamp case constructed of tin, lined with a thin sheet of asbestos, and the outside and inside painted and varnished a dark blue. After the lamp was adjusted, I had a blue glass slide so that the light would pass through the lamp and the slide, making it more effective. It now works very well, and I hope that it will enable many of you to perform small operations on the teeth and gums painlessly, without using drugs. In all cases of pain in the jaws an exposure of from two to three minutes will arrest it for several hours. This is true also when it is applied to bruises and sprains, or lacerations. I have extracted several teeth, one at a time, with this improved lamp, and have removed deposits from the roots of teeth that were very sensitive before the exposure.

It may be that the series of mirrors will be an addition to the efficiency of this lamp, but I am not yet prepared to say that it is a necessity to obtain the best results.

THE BLUE LIGHT AND HEAT ON THE GUMS.

For more than two years I have used a small blue light on the gums for two purposes: The first is to cause a relaxation of the nervous tension; and the second, for the purpose of applying heat in connection with the blue light, so as to effect a double object—to prevent the development of organisms and to stimulate the tissues to a return to health. If the deposits are removed from the root of a tooth, and if they are carefully washed out of the pocket and around the gingival margin, this small blue lamp

may be held within one-half to one-quarter of an inch from the gum for from two to three minutes, when the operation is suspended until the next day.

After six daily exposures, I allow the patient to rest for a week, when upon a close examination, if the deposits are found to have been removed, I repeat the exposure for another six days and the case will be practically cured. Great care must be used not to burn the gum tissue. If it be found that all discharges of pus from the pockets have not been arrested by these exposures, I give another period of rest to the patient and repeat the exposure. During the treatments no medicines are used at all, but I thoroughly massage the gums, and the patient brushes the teeth, using a simple powder. There is no objection to the use of any of the non-irritating washes during the treatment.

The ancients were in the habit of using various colored lights in the treatment of diseases, but their systems fell into disrepute because they enveloped them with so much secrecy that only charlatans and impostors applied them. It was not until Finsen and Roentgen placed before the world their discoveries that a renewed interest was displayed in the utilization of various rays in the treatment of disease, as well as the diagnosis of obscure lesions.

These few observations are presented to you with the hope that operations around the roots of teeth and treatment of diseases of the gums may be much simplified, and that the dread of the chair may not deter so many persons from obtaining satisfactory dental service.

CORRESPONDENCE.

AN INSTANCE OF THE ENDOWMENT OF A DENTAL SCHOOL.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—In the discussion that followed Dr. Butler's paper on "The Educational Problem" [*Cosmos* for February, page 172], Dr. Brophy is reported to have asked this question [page 182]: "Tell me, gentlemen, if you can, where there is a dental institution in this world that has an endowment of a dollar?"

No one present at that meeting seemed able to name a dental school that had an endowment. I wish, therefore, through your columns to say that the Harvard Dental School has an endowment of twenty-six thousand dollars. Twenty

thousand of this sum was given by one man, and is known as the "Henry C. Warren endowment."

It occurs to me that the fact, if made known, may serve to help others interested in dental schools to obtain endowments. You will, I think, agree with me that it is only through the medium of large endowments for our dental schools that we can obtain the best in dental education.

Very truly yours,

EUGENE H. SMITH, *Dean,*
Harvard University Dental School.

BOSTON, February 11, 1907.

MIXTURE OF GASES IN OXYHYDROGEN BLOWPIPE.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—The recent announcement in a scientific journal of a new oxyhydrogen blowpipe may be of interest to dentists. It is said that hitherto, in the oxyhydrogen blowpipe, a thorough mixture of the gases previous to combustion was not feasible, owing to the liability of the flames traveling back and causing an explosion in the mixing chamber.

The inventors (of the Société l'Oxyhydrique), knowing that the propagation of the flame in the tube is not instantaneous, but proceeds at a definite calculable rate, get over the explosion difficulty by making the mixed gases travel toward the flame orifice at a higher speed than the rate of the propagation backward within the tube. So long as this speed is

kept up, combustion proceeds only at the orifice, the flame cannot penetrate to the mixing chamber, and internal explosion is impossible.

On reading this, I naturally thought of the Rollo-Knapp blowpipe, which I used a great deal about twelve years ago. Here we have practically an oxyhydrogen blowpipe in which the gases certainly are effectively mixed in a chamber which is a foot or two away from the flame orifice.

A point of interest is, Did Dr. Knapp just miss the idea of applying the principle alluded to? That seems to be quite probable, as I remember well that one of our reasons for abandoning the use of the blowpipe was that the flame did occasionally "strike back" and cause an explosion, the pistol-like crack of which was

rather disconcerting, although it did no material damage to the instrument.

It is easy now to see that such explosions took place whenever the pressure of one or both of the gases fell below that required to produce the necessary speed of travel. But were the instructions given as to the use of the Knapp blow-pipe such as would lead one to believe

that its inventor knew the importance of the speed relation, the application of which we are told has recently been patented in all the chief countries?

Yours truly,

D. M. SHAW.

ROYAL DENTAL HOSPITAL, LEICESTER SQ.,
LONDON, W. C., July 24, 1906.

DENTAL INSTRUMENTS INCLUDED IN SURGICAL EQUIPMENT OF RUSSIAN WARSHIPS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—It is an item of special interest to note that in the "Report on the Russian Medical and Sanitary Features of the Russo-Jap War," by Surgeon Raymond Spear, U. S. N., it appears (see page 77) that according to his observations in Manchuria the instruments supplied to the Russian ships included in his report consisted of a general operating case and a dental case. No special eye,

ear, throat, or nose instrument cases were allowed. With the instruments on board, however, almost any ordinary operation could be performed.

This report was upon Russian ships in the harbor at Vladivostok that saw service during the war.

Yours truly,

WM. C. FISHER.

NEW YORK, November 26, 1906.

FORMALIN AND TRICRESOL FOR PUTRESCENT PULPS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—I can add my favorable expressions to those of Dr. C. L. Rion (Cosmos, February issue, page 158) in relation to the use of formalin and tricresol. In fact, I consider it a specific in such cases. I have used the remedy for about two years, and cannot recall any number of cases that did not respond to this treatment.

I have applied it to teeth containing badly putresced pulps accompanied by pericementitis; and although it is contraindicated to hermetically seal such cavities with any other drug, I have done so with this combination and obtained excellent results.

Yours truly,

M. J. ORTMAN.

NEW YORK, N. Y., February 7, 1907.

PROCEEDINGS OF SOCIETIES.

NATIONAL DENTAL ASSOCIATION.

Tenth Annual Meeting, Atlanta, Ga., September 18-21, 1906.

General Sessions.

(Continued from page 185.)

TUESDAY—*First Session.* (Continued.)

THE subject of Dr. Butler's paper was passed, and the next order of business was the report of the Executive Council, by the chairman, Dr. BURKHART, as follows:

The Council recommends that a resolution which was submitted to them by the delegates to the International Dental Federation representing this association, to the effect that an invitation be extended to the International Dental Federation to meet in the United States in 1908, be adopted, and that we extend to the Federation an invitation to meet here at that time, and that the officers of this association be instructed to formulate that invitation in due form. The Council also recommends that the usual appropriation of fifty dollars be made to the International Dental Federation.

We also wish to report that the chairman of the Committee on Journal, Dr. Kimball, has made a report to the Council, and that this matter, together with the president's recommendations, will be presented to the Council this afternoon by a special committee.

We also wish to report that the resignations of Dr. A. L. Northrop of New York city and Dr. W. P. Dickinson of Minneapolis, Minn., have been accepted.

The report of the Council was on motion adopted.

Dr. C. N. Johnson, a member of the Executive Committee, being absent, the President appointed in his stead Dr. C. M. Work of Ottumwa, Iowa.

The general session then adjourned until 7.30 P.M.

TUESDAY—*Second Session.*

The second general session was called to order by the president, Dr. M. F. Finley, at 8 o'clock Tuesday evening, September 18th.

The Executive Council, through its chairman, Dr. BURKHART, reported as follows:

The Executive Council reports that at its meeting this afternoon reports were received from the delegates of the association to the International Dental Federation, which report was referred to the Publication Committee to be printed in the Transactions.

The Council also reports that in deference to the wishes of a very considerable number of the members of the association, who have felt that the election of officers was held at a time when many could not be present, and for the purpose of giving all an opportunity to express themselves, we recommend the suspension of the rules, and that the election be held tomorrow, Wednesday, at one o'clock.

On motion the report of the Council was adopted.

The general session then adjourned until Wednesday at 1 o'clock.

WEDNESDAY—*Third Session.*

The third general session was called to order on Wednesday morning Septem-

ber 19th, at 12 o'clock, by the president, Dr. M. F. Finley.

The first order of business was the reading of a paper by Dr. A. W. HARLAN, New York, on "The Blue Light and Heat as Therapeutic Agents."

[This paper is printed in full at page 281 of the present issue of the COSMOS.]

Discussion.

Dr. GORDON WHITE, Nashville, Tenn. We all know that the Roentgen ray has been used very extensively and successfully in lupus; and we know, or rather we are supposed to understand, that many cases have been cured in that way. That the various rays have therapeutic power is perhaps not questioned. It is, however, a question in my mind whether the law of suggestion does not play a part in the production of anesthesia by the blue light. This is a subject worthy of consideration, as I said, which may prove of great value to us, and I hope that someone will discuss the subject who knows more about it.

Dr. H. A. SMITH, Cincinnati, Ohio. Experiences have been called for from those who have made use of the blue light. I used it twelve or fifteen years ago. I was called upon once to extract some teeth for a lady, and it was done under the influence of the blue light from the direct rays of the sun. The lady was nervous and emotional to an extreme degree, and being a believer in the effects of the blue light, had had built an extension to her sitting room, which was lined with glass of a blue shade—quite a deep blue—especially in the ceiling. She sent for me to have several teeth extracted in this room. I visited the house, and extracted two teeth on the first occasion without, she said, causing her any pain whatever. In a few months afterward she sent for me a second time, and I extracted three teeth, again without giving her any pain.

I simply mention this to show that it is not a new idea or method. The concentration of the light upon special tissue I think is new, but there is a class of physicians who have great faith in the

use of the blue light for its general effect upon the human body, and this lady was a believer in that theory.

Dr. N. G. SLAUGHTER, Athens, Ga. I would like to ask the essayist if he has ever attempted to extract a pulp under this light?

Dr. HARLAN (closing the discussion). The idea of the use of the blue light is so ancient that there is not a man in this room old enough to be the great-great-grandson of the man who first advanced the theory. There have been many people who have installed in their houses rooms in which to get the benefit of the different kinds of light, principally the benefit of the blue-light bath. When a person is to take this bath he sits in the room for two hours at a time, with the back, arm, or whatever portion of the body he desires to receive its benefits exposed to the blue light. We all know that if you sit in front of a blue light for any length of time you will become drowsy and thoroughly relaxed. If you sit in front of a red light it excites, makes you restless and wakeful. I have experimented a great deal with this blue light, and it has been a wonderful aid to me. When I am to operate on a patient, I simply tell him that I will not hurt him. I then darken the room, and turn on this blue light, and when sufficient time has elapsed go to work without saying anything, and the patient says it does not hurt. I have not attempted to extract a pulp under this light, but I have been experimenting with it for about three years, and Dr. Gordon White was in my office about two years ago and saw some of the incomplete lamps, which are now more complete.

It affords me a great deal of pleasure to present a thought in connection with the utilization of an agent that anybody can handle without deleterious effects to the patient, unless the lamp be placed too close to the face, when it will burn the same as any other ray would.

The next order of business was the report of the Executive Council, through its chairman, Dr. H. J. BURKHART:

I would ask the members of the association to give close attention to the matters which I will bring before you at this time, because in the judgment of the Council they affect the association members more vitally than any matters which have come before the association in a long time. The matter of publishing a dental journal has been agitated for some time, and I am happy to tell you that after a considerable amount of time spent in consultation and discussion, the Council is of the opinion that with the amendments which are to be offered today, and with what can be accomplished by the officers of the association before the next meeting, that, commencing with the next meeting of the association in July or August, you will have a journal of your own. The committee recommends the following amendments to the by-laws, which under the rules will have to be laid over until next year before final action thereon:

Art. V, Sect. 2:

Add to the section—"of which so much shall be set aside as shall be necessary to secure for the member a subscription to the Journal of the National Dental Association."

Art. V, Sect. 3:

Insert after "branches"—"nor be entitled to receive the Journal of the National Dental Association."

(Signed) CHAS. O. KIMBALL, *Chairman*,
E. K. BLAIR,
J. Y. CRAWFORD,

Committee.

The Council recommend that these amendments be presented, and laid over under the rules until next year.

I wish to bring another matter to the attention of the association. It was ordered by the Committee of Fifteen of the Fourth International Dental Congress that the cases containing models, etc., which were exhibited at the St. Louis Congress, be turned over to the Army Medical Museum at Washington. We are informed that that has not been done, and it is recommended by the Executive Council that the association instruct its secretary to request the gentlemen who has charge of these models and cases to at once turn them over to the Army Medical Museum.

On motion the report of the Executive Council was adopted.

Dr. BURKHART then made a report from the Committee of Organization of

the Fourth International Dental Congress, as follows:

It was agreed by this association and the committee acting for it, that a full and detailed statement would be made to this association and to the profession at large at the close of the congress with reference to the receipts and disbursements of the congress funds. I have here the report from the chairman of the Finance Committee, which gives in detail all the sources of revenue to the congress. I have to present also the report of the treasurer of the congress:

REPORT OF THE FINANCE COMMITTEE, FOURTH INTERNATIONAL DENTAL CONGRESS.

Mr. Chairman and Gentlemen,—In submitting herewith the report of the Finance Committee of the Fourth International Dental Congress, we desire first of all to express our appreciation of the courtesy, consideration, and uniform confidence displayed toward us by your committee, and the widespread and universal trust in our integrity and purpose by the profession at large. This mutual trust and confidence left the committee with a free hand and enabled it to enter upon and prosecute its important work to a successful conclusion. On accepting appointment on this committee our first duty appeared to be to study the scope and financial need of the congress, and to formulate, as nearly as might be, an estimate of the probable expense attending its organization and work. Naturally we turned first of all to the published proceedings of the Columbian Congress, thinking that the expense and results of that gathering would assist us materially in the work we had undertaken; but to our surprise and astonishment, no financial report of that congress could be found, and an appeal to the officers, charged with the duty of financing it, threw no light upon the subject whatsoever, so that we were compelled to devise and develop measures of raising money without any assistance from the experience of those preceding us in similar undertakings. The first work of your committee, therefore, and that as a basis upon which to found their efforts, was to formulate a careful estimate of the total expenses probably necessary to organize, conduct, and complete the work of such a congress; secondly, what percentage of the required amount could be derived from membership fees; and thirdly, from what sources the balance of the funds might be procured.

After giving to these questions such study

as time and available experience would permit, it was estimated that from \$28,000 to \$30,000 would be necessary to complete the work along the lines already projected by your committee; and that from \$15,000 to \$18,000 of this amount could probably be derived from membership fees (see minutes of the Chicago meeting of your committee). But just here arose an unexpected and most perplexing problem, occasioned by the decision of your committee already announced, to present to each member the bound proceedings of the congress, for a fee of ten dollars, we having estimated that to report, edit, print, bind, and deliver the Transactions, would cost a sum equal to if not in excess of that fee, so that we were confronted at the start with the necessity for raising from \$12,000 to \$15,000 from sources other than that of membership fees. This, in the judgment of your committee, should be done if possible, without asking for personal subscriptions from individual members of the profession, as is usual with such gatherings.

Four avenues for raising this amount seemed open to us, namely—First, dental exhibits; second, dental societies; third, dental colleges; and fourth, dental manufacturers and dealers. The first of these was certain to yield something, as it had been already decided to make dental exhibits a feature of the congress; the second seemed reasonably certain, as we felt sure that the whole profession was deeply interested, and through its organization would do what it could to make the congress a success. The third was somewhat problematic, as most if not all of our schools were experiencing difficulty in meeting their own necessary expenses; while the fourth was felt by many to be without any promise whatsoever. However, the needs were imperative, the objects worthy, and it was believed by your committee that upon a fair presentation of the matter the manufacturers and dealers would willingly come to our assistance, and it is with the greatest gratification that we are able to report that in this, as in all other matters pertaining to the finances of the congress, we were not disappointed, as will be shown by a detailed statement of receipts appended to this report.

In all the work of your committee there was nothing more gratifying than the encouragement and assistance which we received from the dental manufacturers and dealers, and we are glad to believe that, in their cordial response to our appeal, something of the unwarranted though real antagonism between them and the profession existing through so many years has been broken down; and if

we are right in thus believing, this result, if it were the only one growing out of this most successful congress, would be worth its entire cost of money and effort. Two other experiences were also extremely gratifying to your committee, and we believe they will be also to the entire profession—namely, first, that every subscription to the Congress Expense Fund that was made unconditionally was paid promptly and in full; and second, that out of the hundreds of personal checks received from almost every city and town in the United States, not a single one was protested—a showing we believe not experienced in any other enterprise of like magnitude, and testifying to the high character and honest purpose of the individual members of the congress; and your committee feels that it would be derelict to its privilege and opportunity did it not in this public manner bear testimony to this expression of professional integrity.

The itemized statement of the receipts of the congress from all sources is as follows:

This, as your Treasurer's report will show, is ample to meet all the financial obligations

of the congress in full, leaving a small balance in the treasury.

In conclusion, your committee owes it to itself to state that the total expense for raising this large sum of money, registering the membership, and the many expenses attending it, was about 0.04 per cent., an exhibition in financing dental congresses not previously realized, and only obtainable in this instance because of the fact that the great bulk of the clerical work was performed by the chairman and his secretary, without expense to the congress.

Respectfully submitted,

CHARLES S. BUTLER, *Chairman*,
WALDO E. BOARDMAN,
CHARLES McMANUS,
R. HAMILL D. SWING,
R. M. SANGER,

Congress Finance Committee.

Respectfully submitted,

M. F. FINLEY,
Treasurer Fourth Congress.

ATLANTA, GA., Sept. 17, 1906.

To the Organization Committee of the Fourth International Dental Congress:

Gentlemen,—The undersigned committee, appointed by the president of the National Dental Association to audit the finance accounts of the Fourth International Dental Congress, would report that they have carefully gone over the books, vouchers, receipts, and checks of the treasurer and of the chairman of the Finance Committee, and have found them correct in every particular.

S. H. GUILFORD,
J. P. GRAY,
V. H. JACKSON,
Auditing Committee.

The Congress Committee has this recommendation to make with regard to the balance in the treasury. We recommend that the sum of \$447.78, which will be turned over to the association, shall be set aside as a fund to be used in the interests and for the purpose of establishing a dental journal, and that this shall be used for no other purpose without a majority vote of this association.

This completes the report of the Committee of Organization of the Fourth International Dental Congress, and we have only to say that we return to you who commissioned us as your representatives, our most hearty and sincere thanks for the manner in which you supported us in our work. We received from you our commission, and we now return it to you.

Motion was made and carried that the report be adopted.

Dr. JAMES McMANUS, Hartford, Conn. I wish to offer the motion that this association tender its sincere thanks to the Committee of Organization of the Fourth International Dental Congress for the very efficient and noble work they did during the holding of that congress.

The motion was carried.

The next order of business was the election of officers, and the selection of the time and place of meeting for the next annual session.

Dr. C. S. BUTLER moved that the time of the next meeting be set for the last Tuesday in the month of July.

The motion was carried.

Dr. Butler also moved that the next place of meeting be Minneapolis, Minn.

The motion was carried.

ELECTION OF OFFICERS.

The election of officers for the ensuing year resulted as follows:

- President*—A. H. Peck, Chicago, Ill.
Vice-president from the West—D. J. McMillen, Kansas City.
Vice-president from the East—George E. Hunt, Indianapolis.
Vice-president from the South—George S. Vann, Gadsden, Ala.
Recording Secretary—C. S. Butler, Buffalo, N. Y.
Corresponding Secretary—B. L. Thorpe, St. Louis, Mo.
Treasurer—A. R. Melindy, Knoxville, Tenn.
Executive Council—H. J. Burkhart, chairman; Charles McManus, B. Holly Smith, J. Y. Crawford, F. O. Hetrick.
Executive Committee—T. P. Hinman, V. H. Jackson, C. M. Work.

Dr. CARR moved that the officers of the sections and the other committees to be appointed be left in the hands of the Executive Council.

The motion was carried.

The general session then adjourned until Thursday morning.

THURSDAY—Fourth Session.

The fourth general session was called to order Thursday morning, September 20th, at 12 o'clock, by the president, Dr. M. F. Finley.

The first order of business was the reading of the report of the Committee on Oral Hygiene, by Dr. J. P. CORLEY, Greensboro, Ala., as follows:

REPORT OF THE COMMITTEE ON ORAL HYGIENE.

Mr. President and Members of the National Dental Association,—The dental profession has universally accepted the fact that dental caries is possible only in the continued presence of decomposing organic matter. The source of immunity is, therefore, simple and definite. It is logical to suppose that a scientific profession would, in the light of this truth, adopt a system of prophylaxis; but has it done so?

The status of dentistry finds expression in the school, the journal, and the association. How many schools have a lectureship on hygiene and prophylaxis? Some of the more progressive provide a few lectures, but I know of none that require a special examination on this subject. The journals

occasionally contain a good article on hygiene and prophylaxis, but when compared with the volume of reading matter which they present, preventive dentistry is in but scant evidence.

But, most important of all, that organization which should embody the very acme of dental scientific thought, the National Dental Association—composed as it is of the leaders in the profession, with no purpose save the service of their fellow men—spends at least nine-tenths of its time in the contemplation of the *cure* instead of the *prevention* of disease. And when we remember that the object of the association is to evolve the highest order of service, we are amazed and chagrined.

The clinical feature of the association is a fairly accurate index to the clinical status of dentistry. If you will review the clinic of any dental society, from the dental congress down to the smallest local association, you will find that the burden of dental technique is cure instead of prevention. However, based upon the present conception of the etiology of dental caries, a school which does look toward prevention has come into prominence, but their method and watchword is extension instead of sanitation. It is more rational to eliminate the area of susceptibility by improving the toilet, than by cutting it out and replacing it with a filling material.

However, if the time required, the labor involved, the punishment inflicted, the mental, moral, and physical energy exercised in from one to a dozen extension restorations would not insure the adoption of a hygienic régime, then I agree that extension is not only justifiable but commendable. But the average patient can make extension anterior to the first molar unnecessary. It is remarkable that the men who attract the most attention, and who appropriate the most time are those who are most expert in handcraft and manipulative technique; while the man who teaches his patients to care for their teeth, thus keeping them healthy and sound, has no "beaten path to his door."

One of the most important discoveries developed by the study of hygiene is the fact that the perfect denture in normal use is practically self-cleansing; while, on the other hand, the imperfect denture is not only not self-cleansing, but it presents in addition serious difficulties to the maintenance of a sanitary state.

This fact has brought into conspicuous prominence the science of orthodontia. In fact, it stands by its own merit at the very "head of the river" in dento-surgical science. If we would insure immunity from dental ills, we must institute and maintain a state of consistent cleanliness, and in order to make

this condition maintainable the denture must be complete, the arch symmetrical, the occlusion perfect, and mastication normal.

The next important system contemplated by the hygienist is the construction of all restorations—whether it be of crown contour or the entire crown, by crowning, bridge, or plate—as nearly self-cleansing as possible. Thus the banded crown is falling into disuse, and the gold crown is giving way to the inlay restoration. Unhygienic bridge and plate work, too, are condemned by the honest, intelligent dentist.

The third field opened up by the study of hygiene is the tremendous importance attributed to function. The part played by a grindable dietary and vigorous mastication upon the integrity as well as the environment of the teeth, is just beginning to receive due attention.

The medical world, too, is recognizing the profound systemic influence of wholesome, vigorous, enjoyable mastication; and, consequently, is compelling the food manufacturers to put grindable food upon the market. Wholesome, vigorous, enjoyable mastication without an efficient dental armature is difficult, therefore the greater need, from a systemic standpoint, of an efficient masticating apparatus.

We have evolved three systems of prophylactic treatment, which differ more in the method of application than in the treatment itself. Briefly, the treatment contemplates that every free surface of every tooth shall be perfectly clean and polished, and that this condition shall be consistently maintained. The patient is required to remove all organic matter before fermentation takes place, and also to keep all salivary deposits carefully brushed off the teeth and the gums massaged. The system does not assume, however, that the patient will be able to do this so perfectly that caries will be entirely prevented; therefore he is directed, even required, to make periodical visits to the dental office, where the sanitary work may be done by an expert assistant, who is denominated the "dental nurse." The man who has done the most to introduce and establish this system is Dr. M. L. Rhein of New York city.

The next school pleases to call its work the prophylaxis treatment, and differs from the one just mentioned mainly in that it proposes that the sanitary work shall be done by a regular practitioner of dentistry. The most pronounced advocate of this system is Dr. D. D. Smith of Philadelphia.

The third school undertakes to explain to the patient the merits of the prophylactic system, and the evils which result from its non-observance. If he manifests sufficient in-

terest to warrant his adoption of the system, he is instructed in the technique of the sanitary *régime*. He is then required to do all of the preliminary work of putting the mouth in a sanitary state. The dentist completes the operation, probably extending the procedure over several weeks' time, until the teeth are free from all deposits, pits, overhanging fillings, etc., and the patient has fully mastered the art of caring for the teeth. He is then dismissed with instructions to return when he becomes aware that his work is failing in efficiency. In cases where incorrectable asymmetries or excessive destruction of the gum and alveoli make it impossible for the patient to maintain a state of cleanliness, he must needs be referred to one of the two previously mentioned schools.

But of the forty thousand dentists practicing in the United States, only a small per cent. belong to any one of these three classes. During the past month I have examined patients hailing from thirteen states, from New York to New Mexico, and a conservative estimate would place the number of dentists who give any instruction in oral sanitation, or who require their patients to observe a prophylactic *régime*, at less than ten per cent. I have had opportunity to observe the methods practiced by the "lay" dentist, and my opinion is that the average dental practitioner does not know what a clean mouth looks like.

It is not uncommon to have a patient say that his dentist told him that the stains on his teeth were a protection, and should not be removed. It is still more common to hear him say that he has been warned against the too frequent use of abrasive powders, for fear of wearing the enamel off of the teeth; many laymen give the same reason as their excuse for not using the tooth-brush.

The subject of a popular treatise on oral hygiene has been before this body for several years. It offers many possibilities, but its accomplishment is attended with many difficulties. The treatise would deal extensively in details, and in this field there is such a diversity of opinion, even among recognized authorities, that the work must necessarily be done by one man. However, should a practical treatise be once published under the auspices of the National Dental Association, it would undoubtedly be accepted by a majority of the ethical practitioners of dentistry, both within and without the association, and would find no competitor in the field.

If the association adopts the President's suggestion that the sum of \$250 be appropriated to defray the expense of publishing a first edition of one thousand copies to be distributed among the profession, giving

one to each member of the National Association, and placing the rest in the hands of the state and local societies, with a subscription blank attached, it is possible that a sufficient number of sales could be secured to pay the expense of another and larger edition. There are thousands of patients who would gladly pay for such a work, and it would save the dentist many tedious hours of instruction.

I believe that a satisfactory work could be sold at twenty-five cents, provided the author gave his services without remuneration. I think that such a proposition would be forthcoming, especially if he were promised a small royalty on all editions after the first. The scheme is well worth the experiment, for it would at least open the way to something better.

The National Dental Association should exercise a paternal interest in every dental association and every dental practitioner in the United States. Whatever helps to shape the status of dentistry, whether it be the college, the examining board, or the society, comes within the association's legitimate field. The committees of the National should so direct their efforts that every dental organization in the country would be inspired to do better work.

The Committee on Oral Hygiene, in order to accomplish work of definite value, should have an auxiliary organization in every state society. These subcommittees should have immediate charge of the work in their several territories. They could apportion it out to local societies or to individuals, as opportunity and expediency suggested.

The central committee would study the question in a general way, make general rules and suggestions, and collect annual reports for data. The National Dental Association could in this way do a work of evangelization which would contribute more to the real science of dentistry than could be done through any other channel.

The *personnel* of this committee should be constituted of men of prominence who are practical and enthusiastic, willing to work without the fear of punishment or the hope of reward. The committee should be appointed from the members present before the adjournment of the meeting, so that they might hold a meeting before adjournment, for the purpose of organizing and planning the year's work. Each man could be assigned to some special feature of the program, thus relieving the chairman and secretary of the burden of the work, and at the same time accomplishing it in a more systematic and influential way.

The committee should be composed of men of broad-minded liberality, or else it would

be impossible to arrive at any definite agreement as to the plan of action. This was abundantly demonstrated in the experience of the present administration. The work of the committee was effectually blocked by one man, who would neither suggest a plan nor agree to any plan suggested and indorsed by all the other members of the committee. Owing to a lack of unanimity the committee could undertake nothing as a body, consequently about the only work done was that for which the chairman assumed the responsibility.

The following circular letter was sent to all state associations, by the secretary, Dr. Stiff:

*Mr. President and Members of the—
State Dental Association:*

Inasmuch as the purpose of dental science is to put into operation the laws of oral hygiene, and remembering that many practitioners of dentistry, as well as the general public, are unversed in the science of prophylaxis, the chairman of the National Association's Committee on Oral Hygiene requests that each state association create a standing committee on oral hygiene, whose duty it shall be to promote the cause among the members of the profession, and through them to educate the public.

He desires, further, that these committees shall constitute a subcommittee to co-operate with the committee from the National, in an effort to establish the fact that oral hygiene is the very basis of dental protection.

Please notify me, through the secretary, Dr. Stiff, what action you may take in the matter.

J. P. CORLEY, *Chairman,
Committee on Oral Hygiene, N.D.A.*

The following letter was also sent to all state associations:

*Mr. President and Members of the—
State Dental Association:*

I am requesting that your state examining board give a practical and theoretical examination on oral hygiene and dental prophylaxis. I am also requesting the dental colleges to put in a professorship, or at least a lectureship on the subject.

I desire that you shall pass resolutions indorsing the measure. Please notify me, through Dr. Stiff, the secretary of the committee, what action you may take in the matter.

J. P. CORLEY, *Chairman,
Committee on Oral Hygiene, N.D.A.*

The following letter was sent to the various state examining boards:

Universal recognition of prophylaxis as the highest expression of dental science impels

the chairman of the National Dental Association's Committee on Oral Hygiene to request that the ——— State Dental Examining Board give a theoretical examination on the fundamental principles of oral hygiene and dental prophylaxis, and that each applicant for license, at the conclusion of his specimen clinic, be required to point out and describe the procedure necessary to put the patient's mouth in a thoroughly hygienic condition. Also, that he instruct, in your hearing, the patient in the best method of keeping the teeth and mouth in a healthful condition.

Please notify me, through the secretary, Dr. Stiff, what action you may take in the matter.

J. P. CORLEY, *Chairman,*
Committee on Oral Hygiene, N.D.A.

However, the matter was put into the hands of the secretary so late that action by most of the associations had to be deferred until next year. The Alabama association elected a committee and indorsed the request made to the examining board and colleges. Their committee is now at work canvassing the dentists of the state endeavoring to get the "rank and file" into line.

The chairman of your committee requested of the National Association of Dental Faculties and the National Association of Dental Examiners the privilege of presenting the matter suggested in the foregoing circular letters.

The National Association of Dental Faculties had such a full program that they were unable to entertain the request, but through the good offices of Dr. Chase, a member of the committee and also a member of the National Association of Dental Examiners, the matter was presented to the Dental Examiners, who very kindly extended the courtesies of the floor to the chairman of your committee, and after an interesting discussion by a majority of the association, the following motion prevailed:

"RESOLVED, That it is the sense of the National Association of Dental Examiners that each state dental examining board include in its curriculum five questions on Oral Hygiene and Dental Prophylaxis."

After the adjournment of the National Association of Dental Examiners and the National Association of Dental Faculties, the conference committee of the Examiners Association presented the matter to the conference committee of the Faculties Association, who approved of their action and agreed to give the matter due attention. This is the most substantial encouragement which your committee has received.

The latitude and functions of this committee have never been discussed by the asso-

ciation. My closing request is that the matter be taken up and fully canvassed at this time, so that your next committee may plan their work with the conscious approval of the association.

Dr. H. J. BURKHART, chairman of the Executive Council, presented the report of the Committee on Journal, as follows:

REPORT OF THE COMMITTEE ON JOURNAL.

To the National Dental Association:

During the meeting of the National Dental Association at Asheville, N. C., in 1903, the suggestion was made that the National Dental Association should take over the *International Dental Journal*, free of all debt, with an assured position, with a list of subscribers and advertisers; and an expression of the stockholders of that journal present showed that all except Dr. Crouse were in favor of giving that journal to the National Dental Association.

A committee was appointed to consider the matter and report. The next year, 1904, being the International Dental Congress at St. Louis, there was no meeting of the National Dental Association and no report from this committee.

At the Buffalo meeting in 1905, the president in his annual address recommended that the *International Dental Journal* be taken over, and that a committee be appointed with power to act. The Committee on the President's Address recommended that the association should have a journal of its own, and a committee of three should be appointed to devise ways and means to this end. At the suggestion of Dr. Crouse the number was increased to five.

Dr. H. L. Wheeler then offered a resolution "That the report be adopted with the amendment as offered, and that a committee of five be appointed by the chair to consider ways and means to bring this about, and if necessary with power to act." This was carried. At the evening session of the same day the committee was appointed, consisting of Drs. C. O. Kimball, W. H. Potter, Herbert L. Wheeler, L. G. Noel, and E. MaWhinney. The last named not being a member of the National Dental Association, Dr. B. Holly Smith was appointed by Dr. Finley to fill the vacancy.

The Committee on the Journal, at the very moment of its appointment, found upon inquiry not enough funds in the treasury to warrant it in accepting the offer of any of the publishers who submitted figures for publishing the *International Journal*, the Lip-

pincott prices being the highest of any, much greater than they had been receiving. Besides this, at the first session of the association, action had been taken shutting out various reputable and independent societies from membership in the National body, several of these societies being the ones that had pledged moral and financial support for the hoped-for independent journal. These were forced by the action of the National Dental Association itself to withdraw the offer of support they had so generously made.

The action of the National Dental Association—giving away their proceedings, and excluding the independent societies, and the low state of the treasury—made it absolutely impossible for the committee to secure either publishing material or financial support enough to warrant them in taking over or securing by contract the *International Dental Journal*.

Meanwhile the board of directors of the *International Dental Journal* had taken action so as to legally turn that journal over to the National Dental Association in case their offer to give it to the association was accepted, but, finding that the proceedings of the National Dental Association for the year 1905 had been given away and their offer not promptly accepted, they decided to close up the affairs of the *International Dental Journal* and suspend its publication. Your committee endeavored to induce them (the board of publishers of the *International Dental Journal*) to keep the journal alive for another year, until the proceedings of the National Dental Association for the year 1906 would become available, and to give the time necessary to effect the change of ownership and management, and various members of the New York Institute of Stomatology, who were also on the board of directors of the *International Dental Journal*, endeavored by every means possible to persuade the magazine to continue another year, even promising substantial financial support. This was done in the hope that on second thought the National Dental Association might rescind its action of 1905 and again welcome members from reputable independent societies. All was of no avail. The board of directors of the *International Dental Journal* refused positively to continue publishing the journal for another year; so that it would cease in December 1905—unless at three weeks' notice your committee would undertake the whole management of the journal, finding editor, publisher, and advertising, without material from the association to publish or funds to draw upon.

Your committee believes that the offer of the *International Dental Journal* was a generous and useful one, but that it was made under such peremptory conditions as to make it practically impossible to accept it, unless the proceedings for the year had been placed at its disposal and a considerable sum of money set aside to meet necessary expenses connected with its management, and this done immediately, without thorough investigation or preparation for the transfer on the part of the association—which it seems to us was unreasonable.

Being unable to obtain a new lease of life for the *International Dental Journal*, various independent societies immediately took steps to organize some form of journal in which to publish their several proceedings, as they were unwilling to give the control of their proceedings to any journal controlled by and issued in the interests of a supply house.

Those societies have decided to publish their proceedings themselves, making the annual dues of each member cover his subscription and pay for the expenses of publication according to the number of pages of matter furnished by each society and the number of copies sent to members, the contribution of each society being controlled by its own editor, each society being responsible for its own utterances; the general management being vested in a committee from all societies.

Your committee knowing what was being done in this line, met in New York on December 5th, and after much discussion on the subject it was resolved to "defer action until we have the results of the attempt of the New York Institute of Stomatology and others to publish their own proceedings, in the hope that it will furnish us with new light upon the subject."

The first number of this new journal appeared in April, the intention being to publish it quarterly unless the National Dental Association should join in the enterprise, in which case it would be published oftener. The second number should have appeared in July, but owing to the necessity of the societies joining in the publication taking formal action to set apart funds for subscription to the journal for its members, in order to comply with the United States postal laws, that issue has been greatly delayed.

The cost of the new journal (including printing cover, binding, printing text, wrappers, directing, and mailing) is \$1.80 per page for a quarterly publication of one thousand copies. Making of half-tone plates is extra. Printing illustrations, cost of glazed

paper, etc., amounts to \$1.57 per page. At this rate the cost of publishing the contents of the "Transactions of the National Dental Association for 1904 and 1905," in magazine form, would have been about \$1000 or \$1100. This does not include cost of editing the transactions, but on the other hand it provides for no advertisements, which would more than meet the total expense. So that when the publication is fairly under way there should be left over a profit for the association.

Your committee, believing that it is desirable to make a beginning in this matter now, to that end recommends that arrangements be made with the societies publishing the above journal, to join with them in publishing its proceedings under the same conditions upon which they do.

And in order to conform to the postal regulations of the United States, we recommend that an alteration be made in the constitution by which part of the annual dues of each member be set aside to pay for his subscription to the journal (see action of the American Medical Association June 16, 1875), and if necessary that one or two dollars be added to the annual dues of this association to defray the cost of the journal, and that the Publication Committee be instructed to carry out these recommendations.

We also recommend that steps be taken to enlarge the National Dental Association by admitting upon equal terms all reputable practitioners of good standing in reputable societies, and to this end we recommend that a committee be appointed at this meeting to revise the Constitution and By-laws.

CHAS. O. KIMBALL,
HERBERT L. WHEELER.
B. HOLLY SMITH,
L. G. NOEL,
W. H. POTTER,

Committee.

The next order of business was the report of the Committee on Army and Navy Dental Legislation, by Dr. WMS. DONNALLY, Washington, chairman.

[The substance of this report has already appeared in the communication of Dr. Donnally in COSMOS for November 1906—vol. xlviii, p. 1104. It will appear in full in the volume of Transactions.]

Dr. CRAWFORD. In view of the very great importance of this question, and in view of the limited time in which we have to consider it, and the great danger of moving somewhat precipitately, I make

a motion that we extend to the chairman of this committee, and the members of the committee, our sincere thanks for the constant and vigorous efforts that they have made along the line of legislation pertaining to the question of dental surgeons in the army and navy, and that a committee of five be appointed to act in conjunction with the President and Executive Council to control the matter of legislation.

The motion was carried.

Motion to adjourn was then made and carried.

THURSDAY—*Fifth Session.*

The fifth general session was called to order Thursday evening, September 20th, at 8 o'clock, by the president, Dr. M. F. Finley.

The first order of business was the report of the Executive Council by Dr. A. H. PECK, secretary. The report included the following item:

On behalf of the Jamestown Exposition Dr. Thorpe requested a provisional loan of five hundred dollars. After some discussion the Council by vote recommended that if after a time the funds in the treasury permit, one, two, or three hundred dollars, according to which amount can be spared, be donated to the Jamestown Congress, with the proviso that the amount shall be refunded by said congress, should the funds of the latter permit.

On motion the report was adopted.

The report of the Committee on Necrology was next presented, embracing obituary notices and appropriate resolutions referring to the decease of Drs. Chas. C. Chittenden of Madison, Wis., John A. Chapple of Atlanta, Ga., and Chas. W. Stainton of Buffalo, N. Y.

On motion the report and resolutions were adopted.

Dr. C. S. BUTLER moved that as there was no member of the Committee on the President's Address present to make a report, the report be referred to the Publication Committee.

The motion was carried.

The report as subsequently handed to that committee was as follows:

REPORT OF THE COMMITTEE ON THE PRESIDENT'S ADDRESS.

Mr. President and Gentlemen:

Your committee desires to congratulate the association upon the able character of the President's address. It exhibits a watchful interest in the welfare of the association and the profession generally.

We respectfully report the following recommendations:

(1) We recommend the appointment of a committee to assist in the revision of the U. S. Pharmacopeia that may confer with Dr. H. C. Wood and request representation.

(2) We recommend the concurrence of this body in the action of its officers in incorporating the National Dental Association.

(3) We also recommend the approval by this body of the action of its officers in contributing \$250 to the San Francisco Dental Relief Fund.

(4) We recommend the appointment of a committee to secure the passage of a law appointing a dental assistant curator for the Army Medical Museum and Library, who shall be a dentist.

(5) We approve the suggestion of employing someone to devote his entire time to research work, but your committee does not feel that the funds of the association would warrant any appropriation at the present time.

(6) We heartily recommend the suggestion of the president to support the efforts of the Committee on History. Every member of this association should subscribe to Dr. Guerini's work.

(7) Action having been taken by the Executive Council in regard to the publication of a journal by this body, no further recommendation is necessary on the part of your committee.

(8) The section work as carried out at this meeting has been so satisfactory that we heartily concur in the recommendation of the president, and suggest the continuation of the present plan until the membership has so increased as to make a change necessary.

(9) We suggest the adoption of a rule requiring all essayists to furnish a synopsis of their papers in time for the appearance of the same in the program issued prior to each meeting.

(Signed) B. HOLLY SMITH, *Ch'man*,
JNO. I. HAET,
R. M. SANGER,

Committee.

There being no further business to come before the association, the president, Dr. Peck, declared the meeting adjourned until the next annual meeting.

A. H. PECK, *Recording Sec'y.*

SECTION III: Oral Surgery, Anatomy, Physiology, Histology, Pathology, Etiology, Hygiene, Prophylaxis, Materia Medica, and Allied Subjects.

Chairman—G. V. I. BROWN, Milwaukee, Wis.

Secretary—W. H. G. LOGAN, Chicago, Ill.

THE first meeting of Section III was called to order by the chairman, Dr. G. V. I. Brown, Milwaukee, Wis., Wednesday evening at 8 o'clock, September 19th, 1906.

The first order of business as announced by the chairman was the reading of a paper by Dr. GORDON WHITE, Nashville, Tenn., on "Treatment of Pyorrhea Alveolaris."

[This paper is printed in full at page 247 of the present issue of the DENTAL COSMOS.]

Discussion.

Dr. L. G. NOEL, Nashville, Tenn. I believe I was selected to open the discussion on Dr. White's paper because I was at one time associated with him, and am still practicing in the same city with him and can tell what he is doing along this line. He has produced some very marvelous results in the treatment of these cases, and it gives me great pleasure to state that he has thoroughly mastered many cases that would baffle almost any

of us. In beginning his treatment he succeeds in impressing his patients with the fact that he is master of the situation, and he dominates and controls them to such an extent that they will do anything he demands and believe anything he says, and that is one reason why he succeeds so well with his cases.

I am somewhat inclined to criticize the opening sentence of the paper, in which occurs the phrase, "how I cure pyorrhea." Now I object to that because I do not believe anybody ever *cures* pyorrhea, but rather only relieves the condition. The essayist states farther on that the patients who follow his suggestions as to constitutional treatment, and come back for local treatment faithfully, are the cases in which he obtains his best results—a statement that will coincide with the observation of most of the older practitioners.

Dr. White succeeds in impressing his patients with the serious nature of the disease, and I can say that he gets results that are very wonderful to me, and which I have very seldom seen in the hands of other practitioners. I wish he had exhibited the instruments that he uses to remove the tartar. He has in addition to his power to impress the patients with the evil results of this disease, a wonderful touch in the removal of the deposits. It has always been my belief when the disease has extended beyond the bifurcation of the roots that the case is hopeless, but Dr. White will often amputate a root and save parts of teeth only, for the attachment of the crowns, thus bringing about wonderful results.

It gives me great pleasure to state that I have seen many of the cases years after his treatment, and it has been a surprise to me that the original condition of inflammation in the gums had not set in again.

Dr. A. W. HARLAN, New York, N. Y. I have been very much interested in the pictures presented by Dr. White and have seen some of the models, in fact I have seen all of them, and must say that the results of this treatment are apparently very satisfactory.

In the treatment of loose teeth we must

recognize certain things. At the present time the question of the causation of this condition is still in dispute, because there are many factors to be considered in the matter. We have some constitutional diseases and we have some local troubles to contend with which must be recognized. The man who, when standing before you, continually blows his breath at you, is one who is a victim of what might be considered a potent factor in the causation of loose teeth—mouth-breathing.

The illustrations in Dr. White's paper explain themselves, but we must go back of that. There are many conditions contributing to the causation of loose teeth, which have not been considered fully in any paper or presentation of this subject. I only have to say that I believe, in order to arrest any condition that will cause the loosening of the teeth, there are in addition to constitutional treatment some local operations that are absolutely necessary. The first thing is that the teeth must be held firmly in position; secondly, the roots of the teeth must be thoroughly deprived of any extraneous concretions or accretions of deposits, so that the tissues will have an opportunity to return to their normal shape; thirdly, we must have cleanliness, and that is a matter which every man must determine for himself. We must also have occlusion of the teeth so that irritation may not be kept up by malocclusion, and our object can only be accomplished by cutting and grinding, all of which I think Dr. White has brought out in his paper.

Dr. M. L. RHEIN, New York. Before showing some slides that I wish to exhibit, I wish to personally compliment Dr. White on the results which he has presented to us. What I have to say this evening is entirely on this subject, but upon a somewhat different phase of it. I want to call attention to the fact that in pyorrhea alveolaris, loose teeth, Riggs' disease, pathological conditions of the periodontal membrane, or any other name you wish to use in discussing this subject, the important point to consider is the one that presents itself to every dentist and every physician when any case of disease comes before him, and that is

the question of diagnosis, and what is more important still, the question of differential diagnosis. The two important points to be considered are the exciting cause and the predisposing cause. I wish to especially direct your attention to the fact that the difficulty of treatment of

that if you know what you are treating, you know how to treat the case, and you are also able to tell your patient in advance what the results will be of your treatment.

The slides I shall show you are made from radiographs—not photographs—

FIG. 1.

these conditions—which are such a factor in the destruction of teeth and the reason why the profession at large has met with the poor results of which so many complain—is because the treatment has been pursued in an empirical way. Empiricism has been the retarding factor in the progress of our specialty since I can remember, and as we leave its realm so are we able to advance gradually toward success with our treatment, and bring such results as Dr. White has shown us, not occasionally, but invariably and understandingly. I claim

showing absolutely every portion of the tissue from the enamel down to the end of the root. Necessarily, and unfortunately, slides of this kind on account of their density do not show up so well on the screen as the ordinary photographic slide can be made to show. I therefore ask your indulgence for them in this respect, and will endeavor to make clear the points more easily discernible by those who are accustomed to examine and interpret radiographs.

The first thing necessary in order to formulate a correct diagnosis of condi-

tions of this kind is to know the difference between the physiological normal alveolus and the one in which pathological conditions exist. Now I shall show you two slides of cases where there was a local condition that might be called pyorrhea, but in both cases the alveolus is absolutely normal, and you will notice the great differentiation in the alveoli in these two cases from those which are pathological. The first, Fig. 1, is the case of a monkey that I obtained at the Rockefeller Institute in New York. He was inoculated in the course of investigations on spinal meningitis. This monkey died finally from inanition, and the director of the institute called my attention to the great amount of calculus deposit around the teeth, and I thought we had a good case of pyorrhea; so I turned the specimen over to Professor Broomell, and to our astonishment we found a normal alveolus. This illustrates what happens so often in practice, where we see many cases in which deposits are simply the localized expression of a constitutional disorder. This difference can be seen in the other slides. The density of the radiograph does not enable us to bring it out so clearly, perhaps; however, they show absolutely all of the portions of the alveolus, which is intact. All of the white substance is osseous tissue, and there appears to be no destruction of any portion of it. It shows a perfectly physiological jaw, although there is a great amount of calculary deposit, and it is therefore a most interesting specimen to study in comparison with pathological specimens.

This next case, Fig. 2, was one of a loose bicuspid, and the patient was referred to me as one suffering from pyorrhea and demanding attention. The radiograph, while it shows an absolutely healthy condition of the osseous structure, presents one pathological point: A careful examination of the radiograph shows that inflammation of the pericementum had existed, and that the looseness of this bicuspid was entirely due to local irritation brought about by a badly made gold shell crown, the exciting cause of the inflammation in the peridental

membrane. The removal of the pulp and the proper crowning of the tooth effectually cured the case.

FIG. 2.

Now I will show you in contradistinction one of the ordinary types of pyorrhea in which considerable destruction of the tissues had taken place. (Fig. 3.) Here is the neck of the tooth; the bone

FIG. 3.

is absorbed down to this point [indicating], and although in these cases the gum may extend to its normal position, the bony septum between the teeth may, as here, be lost. The value of the X ray both in diagnostic work and in treatment is exemplified in this case. Dr. Harlan has mentioned one of the axioms in the treatment of cases of this kind, that "Every particle of these deposits must be removed." Now it is impossible for any deposits to be on these teeth that the radiograph would not show. Very frequently, however, the operator is deceived about this thing. Often the patient, as Dr. White has said, will come back, which means that deposits still remain. This X ray shows the accretion on the side of the root most beautifully.

The main thing I have to say is that the X ray is an aid to correct diagnosis; but I do not care to have you construe this remark as meaning that the X ray can be absolutely depended upon, for that would be going to the extreme, and would not be warranted by the facts. In the first place, you must accustom yourself to the examination and study of the X ray in order to understand what you see, and even then we are sometimes deceived. On that account I simply present it to you as an auxiliary in diagnosis.

This next case, Fig. 4, is one that I present to you in order to show where the

FIG. 4.

X ray in itself is deceptive in what it shows. In other words, even one who is careful in making a study of radiographs can be deceived by this picture. We have an upper second bicuspid, with a light line surrounding the apex of the root. When you see an area of this nature anywhere around the root of a tooth in this condition, it is an indication of the existence of an abscessed condition, and is one of the most valuable diagnostic signs we may obtain with the radiograph. It invariably reveals pericemental abscesses in teeth with vital pulps.

This is a case that was transmitted to my care by my father-in-law about fifteen years ago, and which had been in his hands for a number of years. (A great many of the members present will undoubtedly still remember the name of Dr. Odell.) In the treatment of that patient's mouth I was careful to avoid doing anything to this tooth, because it was a beautiful restoration of a tooth with

a gold filling that had been in place up to a year ago for over thirty years. About a year ago the patient complained of neuralgic symptoms in this region, and to aid in diagnosis I made this radiograph, which fails to disclose any root-filling. I had supposed that this large gold restoration was over a pulpless tooth with a root-filling in it. You see how plainly the radiograph shows a loss of root tissue—the tissue being absorbed at the end of the root with this long-standing abscess around it. This had finally proceeded to such an extent as to cause severe pain to the patient. Now here is where the radiograph deceived me. In exploring the root-canal I found to my astonishment that that root was thoroughly filled to the end with cotton. I had never seen a cotton filling before that did not smell. There was no odor from it, and it was packed tightly to the end of the root, and was one of the most difficult fillings I ever had to remove. I simply call your attention to the fact that the cotton root-filling does not show up.

You will notice in the adjoining first bicuspid which I had crowned some years ago, the root-filling extending to the end of the root quite distinctly. This case was entirely cured by means of the electrolytic treatment. The electrode was passed through the opening in the root into the surrounding tissue, the area absolutely disinfected, and the root-filling restored—a very satisfactory result ensuing.

The next slide, Fig. 5, shows a loose

FIG. 5.

lower third molar with deposits and pus, a type of case that a large portion of the

profession would take for a pyorrheal case pure and simple. This was my opinion until I took an X-ray picture, and found this amalgam filling entering the pulp-cavity, with no sign of the pulp ever having been interfered with. It turned out to be simply a case where the exciting cause was an improperly inserted amalgam filling which had caused the death of the pulp.

The next picture I ask you to notice. Fig. 6, shows an upper lateral with vital pulp and a pericemental abscess at the apical region. This patient is a member

FIG. 6.

of the New York State Dental Society, and came to me with a pyorrheal condition of the mouth, and this tooth, a lateral, was the one most affected. The picture shows the pyorrheal condition of the tooth, with the absorption progressing at the end of the tooth. The removal of the pulp and the filling of the root cured the case.

The next case, Fig. 7, is a case of marked pyorrhea that I would designate

FIG. 7.

as gouty—pyorrhea arthritis—a case in which the condition is most marked.

The pulps are almost obliterated by the filling up of the pulp-chamber with secondary formations. These are the cases that give trouble in treatment, because of the difficulty in filling such canals to their ends.

The next slide, Fig. 8, is a case showing a marked condition of pyorrhea

FIG. 8.

around a lower molar, complicated with an alveolar abscess. The next molar has been properly treated by removing the pulp and filling the canals. I want to call your attention in this radiograph to the differentiation of the tissues, and also to the inferior dental canal, which is distinctly running along below the molar.

The next case is a very interesting one, and will be shown by the four succeeding slides. The first slide, Fig. 9, shows an abscessed condition over these bicuspid. In the molar is the evidence of an old root-filling of one of our ablest dentists in New York city. The lingual root had been partially lost, and the filling is seen protruding beyond the absorbed end of the root. The next slide, Fig. 10, shows the opposite side of the same patient's mouth, where the conditions are worse. This patient was referred to me to see if I could possibly save these two loose molars. A great many dentists had seen the case, and all claimed that the teeth were so loose that nothing could be done with them. They were almost ready to drop out of their sockets; it is hard to realize how little retention they had. You will notice that an attempt has been made to open into the buccal and lingual canals of these teeth, which was unsuccessful on account of the filling up of the canals with secondary matter—but it is useless to treat

such cases unless the canals are cleaned and filled to the ends. The next slide, Fig. 11, shows these two molars after the buccal canals have been properly filled. There was no attention paid to the lin-

teeth, the simple removal of the pulps and reproducing the lost lingual root, was not all that was necessary. It was necessary, as the preceding gentleman has said, to hold the teeth fixed. I am

FIG. 9.

FIG. 10.

FIG. 11.

FIG. 12.

FIG. 13.

FIG. 14.

gual roots in either of these teeth, because both the lingual roots had lost all of their attachment and had become necrotic appendages which had to be amputated. After removing the roots I replaced them by porcelain substitutes, as I have described in some of my papers in years gone by. The mere treatment of these

opposed to the use of bands for that purpose, for reasons which I will not enter into now. The method used here was to run a platino-iridium wire into the porcelain root that was placed in position in the second molar, running it up across the occlusal surface and into the pulp cavity of the first molar. The same con-

dition was observed in the first molar. A platino-iridium wire in the porcelain root was carried across the occlusal surface and into the pulp-cavity of the second molar. All this was done at one operation, and the wires were cemented into place by means of amalgam. The illustration, Fig. 12, shows the finished operation. It shows the porcelain root of the second molar and the platino-iridium pin as it extends and crosses over into the first molar. The dark mass is the amalgam restoration which firmly holds the two teeth together. The porcelain root on the first molar, for mechanical reasons I thought best to leave at the angle shown instead of at right angles, believing that I should thereby get better retention.

And here I want to call your attention to a very vital point in the treatment of loosened teeth in holding them together by splinting. It is usually thought when you splint loose teeth together, that in order to hold them firm it is necessary that they should be attached to a tooth that is not loose. That is a common error. Two loosened teeth splinted together will be firm, for the reason that the roots protrude through the alveolus at such divergent angles that they pull against each other, and produce the firmness which we desire. That is an important point which I do not believe has ever been brought clearly before the profession.

The next and last case I consider also as one of the extreme ones. What I am trying to demonstrate here is that many cases said to be hopeless can be saved. Fig. 13 shows a lower central incisor in the mouth of a young married woman. The alveolar attachment is almost entirely lost. The pyorrheal area is well marked. The pulps of this and of the adjacent teeth were removed and the ends of the canals filled. A splint of the shape of a three-pronged fork was then made of iridio-platinum, attached to three inlays filled into the three pulpal openings and then cemented into the three roots. The last slide, Fig. 14, shows the completed operation.

Further discussion of Dr. White's paper was deferred until after the reading of the next paper.

The chairman then announced as the next order of business the reading of a paper by Dr. H. J. ALLEN, Washington, D. C., on "Lymphatic Stimulation in Dental Practice," as follows:

LYMPHATIC STIMULATION IN DENTAL PRACTICE.

It is only during recent years that the lymphatic system has received from physiologists the attention which its importance demands. All the older physiological text-books give only a vague conception of the mechanism of the system, and few venture to impart any information as to its functions.

The development of special knowledge of these functions has been consequent upon, and coincident with, our increasing knowledge of the bacterial origin of disease. Pasteur, Koch, Behring, Metchnikoff, and Foster have within the last decade made astounding discoveries relating to the functions of the lymph stream, which have revolutionized the treatment of infective diseases in general.

As one of the results of these discoveries a number of pseudo-scientific geniuses have applied the forceps to their respective imaginations, and delivered full-fledged systems of lymphatic therapeutics which they are certain are going to revolutionize the accepted theory and principles of general practice.

Osteopathy, which is the pseudonym under which a large percentage of the public are at present having their lymphatic systems stimulated, bears about the same relation to the regular practice of medicine and its collateral branches that astrology bears to the science of astronomy.

The good and the bad, the true and the false, theories and facts, are merged and cemented together by the imaginative intellects of second-hand discoverers and inventors of systems, who do not hesitate to utilize any fad, fact, or fancy, in order to put their systems on a dividend-paying basis.

Still, under the spangles of the mountebank, true therapeutic worth lies concealed. Vibration administered by

empirics has unquestionably produced in some cases most excellent if not marvelous results, and it must follow that this physical method in the hands of a conscientious and thorough man—one who pays strict attention to his pathology, physiology, and anatomy—will produce results that are almost miraculous in certain cases.

The art of massage and manual manipulation dates from the most remote antiquity. Thousands of years ago the Chinese had written treatises on the subject, and Hippocrates makes frequent references to the subject in his writings. In one paragraph he says, "Rubbing can bind a joint that is too loose, and loosen a joint that is too rigid. Much rubbing causes parts to waste, while moderate rubbing makes them grow."

Hippocrates was also the first to record the employment of mechanical vibration—"wrapping one end of a saw with cloth that was applied to the part to be treated, while sawing a piece of wood with the uncovered portion, thereby producing vibratory oscillations in the affected part."

Galen and Paracelsus also used and advocated similar methods in their practices.

From these remote times until the present, methods of vibration or massage have waxed and waned, until at the present day vibratory massage has come to be recognized by the medical profession as an efficacious procedure in the treatment of numerous local and constitutional disorders. And yet today's researches reveal only how much more complex is the body's metabolism than yesterday we thought it to be, and in the problem of vibratory therapeutics there is certainly much more before us than behind us. Lying as it does on the border zone where the physiologic and the pathologic meet, it reaches far into both, and obscures the division line between them.

In any disease the organism makes a constant effort to recover "that just balance which we call health," and now that it is possible for the physiologic and metabolic forces of the body to be marshalled and intensified in order to assist this effort by vibratory treatment applied with

intelligent persistence, we can but feel that the armamentarium of the medical and of the dental therapist has been greatly increased in efficiency.

A succinct review of the lymphatic system—which is the main function of the body affected by vibratory massage—would not be out of place at this juncture.

The name is derived from the Latin word *lymph*a, water, and in view of the knowledge on the subject at the time this name was given, could well be termed the "water-system" of the body.

The system consists of vessels and glands that commence in a series of lymph capillaries in the organs and tissues of the body, and terminate in two large trunks which open into the larger veins near the heart—the thoracic duct on the left and the right subclavian trunk on the right. The vessels are very thin, vary from transparent to translucent, and permeate all tissues excepting the non-vascular structures, such as the hair, nails, and the enamel and dentin of the teeth. They are beaded in appearance, being interrupted in their course by constrictions which lately Foster and Ziegler have agreed are valves which act similarly to those of the veins, and serve to give impetus to the flow of the lymph.

The glands of the system vary in size from that of a small seed up to that of an almond, and are situated in the course of the vessels. A lymphatic vessel, before entering its gland, breaks up into several branches which are known as afferent. The vessels as they leave the gland are called efferent.

The lymph capillaries are made up of a single layer of endothelia, whereas the larger vessels and glands have a middle muscular coat and an outer adventitious one. This structure at once makes apparent the perfect drainage the lymph capillaries afford the tissues, and the mechanism by which the products absorbed by the capillaries are passed on by muscular contraction to the larger vessels *en route* to the point of elimination.

The lymphatic glands are now confidently claimed to be the points of origin of the white blood corpuscles—or phago-

cytes—and Metchnikoff was the first investigator to direct particular attention to the important part played by these lymphocytes or corpuscles in maintaining health and destroying pathogenic germs.

Here it may be mentioned that the general tendency is to overlook the absolute importance of the lymph flow of the body, and to think of the blood as the sole nutrient fluid of the economy, but the fact is that the blood nourishes the tissues only through the agency of the lymph. Sir Michael Foster calls lymph the "middle man," by means of which a double interchange of material takes place between the blood within the capillaries and the tissues outside of them. The rapidity of the process can be partly comprehended by the fact that it is estimated that the entire volume of blood passes through the lungs once in every twenty-four seconds.

In addition to giving origin to the lymphocytes and acting as temporary reservoirs for the lymph, the glands also drain the tissues adjacent to them, and are consequently important factors in the process of absorption.

Lymph comes into more intimate relation to tissue metabolism than even the blood, conveying as it does nutriment to the tissues, and receiving from them in return the products of cellular activity. Lymphatic glands are therefore both secretory—producing the lymphocytes which become converted into phagocytes after passing into the blood—and excretory—draining the waste matter from contiguous tissues and discharging them into the circulation; and both of these functions are performed simultaneously. They are prone at times of lessened vitality to become overloaded with waste or poisonous products, which partly inhibits their function.

These glands, although rather sluggish in their natural action, are highly responsive to stimulation, and their excretory function may be very materially increased thereby. There is but little doubt that their natural torpor arises from the toxic effect of the waste and deleterious matter which drains into them from the

surrounding tissues, and for which they act as reservoirs.

From this rather hasty review of the structure and functions of the lymphatic system, it will readily be seen that it is of supreme importance in the general metabolism of the body, and the perfect functioning of the economy depends absolutely upon the integrity with which the lymphatic system performs its dual office.

Now as to the therapeutic aspect of the subject. The results obtained from the practice of vibratory massage by the most competent practitioners may be epitomized as follows: (a) Energetic stimulation of the lymphatic and arterial vessels and glands; (b) Dispersion of exudations; (c) Increased secretions of the mucous membranes and glands.

As a general proposition it may be said that the method can be used with the greatest success in all subacute and chronic diseases. Dr. Lorenz has recommended it in chronic joint diseases, and has also suggested its employment after any operation in which it is desired to increase the nutrition of the part and to hasten recovery.

Dr. S. J. Meltzer of the Harlem Hospital, New York city, has stated, as a result of a series of experiments, that the growth of bacteria is absolutely inhibited by continued vibrations. Similar reports have been made by foreign investigators.

In view of such a range of therapeutic activity, the application of this method to the treatment of pyorrhea alveolaris and alveolar abscess is apparent.

In the treatment of pyorrhea alveolaris, after the thorough scaling of the roots of the affected teeth and the complete disinfection of the pockets with iodine, zinc iodid, or any of the acids used for the purpose, the patient is ordinarily dismissed with more or less explicit instructions to take excellent care of the teeth and mouth. This is where a mistake is ordinarily made. The operator should not dismiss the patient until after the complete convalescence of the gums, and until he is assured that the care he has advised is exactly suited to the individual case under treatment. This care

should invariably include stimulation of the lymphatics of the gums by massage, administered by either patient or operator or both—the patient using either a rubber cot brush, towel, or finger; the operator at such intervals as his judgment dictates either applying or advising the application of mechanical vibratory stimulation by the appropriate apparatus—a variety of which have been placed upon the market.

Thus the lymphatic system of the gums will be kept so active that exudations will be either prevented or more readily absorbed, and the progress of the disease will be reduced to a minimum.

I tell patients suffering from this disease that the amount of trouble they will have from it will bear a persistent ratio to the lack of personal care and professional treatment—emphasizing both personal and professional treatment as of equal importance, each one supplementary to but under no circumstances a substitute for the other.

When the common membrane of a tooth and its socket becomes inflamed from any cause and its structure infiltrated with serum, how is the surplus serum—that amount in excess of what is needed to repair the parts or restore them to a normal or approximately normal condition—how is that excess to be disposed of? By one of two methods; either the lymphatics of the adjacent tissue must absorb it rapidly enough to prevent disintegrating changes taking place, or else the accumulated serum becomes the pabulum of an innumerable host of pyogenic organisms and an abscess results, with or without a fistula, according to the vitality of the patient or the activity of the lymphatics involved.

As to the best method of allaying periodontal inflammation and absorbing the prospective abscess in such cases: If there is any better method than that of first removing the cause, and then stimulating the adjacent lymphatic glands, it would seem that it is yet to be generally learned.

Simply removing the cause will result in a slow cure for the majority of cases, but as the average practitioner always

succeeds in a majority of his cases, we can consider that it is the minority that tests his therapeutic wits, and it is in reducing that difficult minority that lymphatic stimulation gives most brilliant results, and successfully carries a precarious case to a speedy convalescence a sufficient number of times to justify the administration of the treatment in all indicated cases.

In those cases of acute alveolar abscesses presenting for treatment at that stage where the lightest touch is agony for the patient, the quickest method of checking the inflammation and reducing it to the point of permitting instrumental cleaning of the root-canals is to subject the affected side of the jaw to several exposures of blue- or ultra-violet light rays, at the same time applying the rubber applicator of an electrical vibrator to the cervical lymphatic glands of the same side.

In lieu of either or both of the above-mentioned methods, it is well to instruct the patient to refrain from putting any sort of application on the face, but to sit, if possible, with the affected side exposed to the direct rays of the sun for five or ten minutes several times a day, and to stimulate the cervical lymphatics of that side by the use of a little hand rubber massage mallet—or even an ordinary hollow rubber ball inclosed in a handkerchief could be used for the purpose. One to two hundred quick, gentle strokes are usually sufficient for one of the two or three treatments necessary. In unusually severe cases the patient may be instructed to stimulate the axillary lymphatics of the affected side in the same way.

Aside from the positive benefit that results from these measures, the patient's attention is diverted from the seat of trouble, and he is kept busy with a process that gives relief in proportion to the enthusiasm of its administration.

It is now universally admitted that the exposure of any infected tissue to the sun's rays unquestionably inhibits, and in many cases of continuous exposure destroys, the pathogenic bacteria present—the sun being the world's greatest germicide—while the judicious stimulation of

the lymphatics contiguous to the affected area increases both their power of drainage and the process of phagocytosis.

These remedial measures are suggested, and have been successfully used in personal practice, in addition to the classical local treatment in general vogue for the pathological conditions mentioned. There is no intention whatever of offering any substitute for thorough and painstaking local work on affected teeth, but rather that we should add to our present methods additional means of more speedily accomplishing the return of diseased conditions to the highest degree of normality possible under the circumstances. In conclusion, it may be said that experience justifies us in not expecting to obtain uniform or invariable results from any therapeutic system; and lymphatic stimulation through mechanical vibration, like all other therapeutic measures, demands for its successful application a sound pathology, accurate deductive reasoning, and good common sense. While we cannot positively accept all that has been asserted regarding its field and its possibilities, neither can we reject it, and further observation will be required before a final decision can be reached.

The hope is expressed that this article will at least prove fertile in its suggestiveness, rather than in its supply of specific detail.

Discussion.

Dr. J. Y. CRAWFORD, Nashville, Tenn. I have always been pleased with Dr. White's work in dental surgery, as he exhibits a very high type of excellence in whatever he does. I had the pleasure of seeing one of the cases exhibited on the screen, and I can say that the results were very satisfactory indeed, from the standpoint of my judgment. I think, however, that the principal value of Dr. White's paper, added to its pleasing presentation, is the very marked suggestion that he threw out—alluded to also by Dr. Rhein—as to the importance attaching to the question of differential physical diagnosis. I am very well satisfied that a great many of the cases that come under the care of the dental sur-

geon could be treated by pursuing a more conservative course. I think there is a tendency to go a little too far, owing to the anxiety and the enthusiasm of the dental surgeon.

If I understood Dr. Rhein correctly—in which case I must hold that his teaching is erroneous—the gist of his remarks was that it is a very common thing for the apical end of a root of a tooth to be bathed in pus with a living pulp in it. According to my experience clinically, I must say that it is a very rare thing for the end of the root of a tooth to be enveloped in pus and the pulp remain living in that canal. I do not pretend to say that such a thing does not exist as a pus-investment of the entire end of a root of a tooth, and yet vitality remain. The vital structures, and particularly the nerve tissue, are remarkable in their power of resistance to the progress of disease action as a rule; but how often have the older practitioners seen the vitality in the palatal root of an upper molar destroyed and a provisional zone of partition thrown across the pulp-chamber, and the two buccal roots living. All men have seen that who have been long in practice. Show me a dental surgeon who has not observed such conditions, and I will show you one who either has not had much practice, or else he is a very poor observer. These things do occur, gentlemen, but to say that they are common occurrences in practice is erroneous teaching.

With regard to the diagnostic value of the radiograph: If I understood him correctly, Dr. Rhein said that by means of the radiograph he proposes to show the different pathological changes taking place in the tissues within the time covered by that radiograph. Later on he told us that that white zone or field was an indication of pus. Now, gentlemen, if that be true in every picture that he showed us, there was pus all around the teeth.

I was very much interested in the composition and statements made in that last paper, for if there is anything in the world I like, it is clinical reports. Not many practitioners know how to make

a clinical report. The average person presenting a case announces the diagnosis and then reports the case. He should first report the case, and then give his opinion as to the diagnosis. Why? Because you should want everybody to study the case with you. I tried to cultivate my powers of diagnosis in keeping with the valuable suggestions of Dr. Rhein, and by listening to the statements he made and looking at the pictures, tried to make up a diagnosis of the cases, but he gave his diagnosis before he told us all.

When Dr. Allen read his paper, I tried to determine whether it was hydropathy or osteopathy, or what it was he was teaching, but I do not know. But I will tell you, gentlemen, if I had a case of pulpitis that was not amenable, not in a few days but in a few minutes—a case where the lymphatics were involved—well, bring such a case in here to me tonight, and if I don't afford relief to that case in twenty minutes, I will quit practicing dental surgery. How many dental surgeons have not had many cases of the type he presented here tonight, which were the result of pent-up pus! One step more, clinically: I do not believe that the surgeons of the world, and particularly the dental surgeons, have ever grasped the significance of the immense amount of force developed in the process of inflammation that takes place in and around the teeth. The amount of force developed in the process of inflammation and the formation of an abscess is often sufficient to burst a tooth, and many teeth are split open under it. Has not every dental surgeon observed what I call your attention to tonight? If not, one of two things is sure; either he has not had much experience in such cases, or he is a very poor observer. Every dental surgeon has opened an upper lateral incisor and seen the pus come boiling out. Perhaps in another case they will open a tooth and the pus will not come out. Why? The elasticity of the structures around the tooth has been so overcome that they do not respond; while in the other case the structures are so elastic that they squeeze the pus out. Every practitioner has seen this. Now, instead

of pummeling that fellow with a sore jaw, give vent to this pus area, and let nature do the rest.

Dr. M. F. FINLEY, Washington, D. C. I would like to say just a word, not so much on the paper as on the last discussion. It seems to me that our friend Dr. Crawford has misinterpreted the cause of pain in the cases that the essayist presented. In a great many cases pain is present when there is no pus, or we might say with certainty that in the majority of cases where pus has formed the pain ceases. The stages preliminary to the formation of pus are the ones in which the greatest pain is encountered. I think it is quite reasonable in a discussion of this kind to give credit for discrimination in the diagnosis to the one who prepares and presents a paper. One of the greatest drawbacks to successful practice is the failure to make a proper diagnosis. Dr. Crawford would have us believe that all cases of pain result from pent-up pus, when in reality there is nearly always a cessation of pain when the inflammation has existed sufficiently long to produce pus. It is to stop the inflammation in its early stages that the treatment suggested by the essayist is here offered, in the hope of cutting short suffering and pain. Our main effort should always be to give relief at the earliest moment possible, and it seems to me a plan is here suggested which will improve our present methods. It is worthy of careful consideration.

Dr. H. T. STEWART, Memphis, Tenn. I have listened to a good many discussions on Riggs' disease, or so-called pyorrhea, but I have not heard in a long time so interesting a discussion as we have heard tonight.

I want to take exception to two or three things; one is that in Dr. White's paper, as in nearly all papers on Riggs' disease, we find emphasis is laid on the removal of deposits. I have always asserted that this is not the chief thing in the cure of the disease. I used to think that it was deposits, and I labored to remove the deposits only. They assuredly should be removed, but men who remove deposits only, do sometimes what we do not take into question—they tear up the

tissues and stimulate new tissue, and afterward apply stimulating medicines to the edges of the alveolar border. I have experimented a great deal along this line, and in a great many cases I have tried to see what results I could get by leaving the deposits alone, and have often obtained results that would astonish me.

Another thing: I think it is altogether wrong to assume that it is local treatment only to which we should direct our attention. I believe that is false teaching. A good many years ago, when I read my first paper on Riggs' disease—and by the way I want to say that I object strenuously to the name pyorrhea as being misleading; and while I do not like the name of Riggs' disease, it is at least not misleading—I stated that in a large percentage of cases we have no pyorrhea at all, but in Riggs' disease we cover the ground. Whether there is pus present or not, it is Riggs' disease. I wish we had a better name, but we have not. Dr. Noel took me to task at the southern meeting in Memphis last year for calling this condition Riggs' disease. I asked for a better name, but Dr. Noel has not given us one. Some present have heard me before cite some cases in which the catarrhal conditions prevented the cure of the case. I want to say today that the catarrhal condition of the mucous membrane of the mouth in the treatment of Riggs' disease is something that cannot be controlled by lactic acid or the removing of the deposits; this is something that is not taken into consideration as it should be, and consequently accounts for the return of the disease in many instances.

Dr. Noel says it cannot be cured, but I say that it can be cured. I remember one case that I treated in which I obtained very good results at first from local treatment, but the patient returned. A specialist from New York city examined the case and found a deflected septum, which caused the man to breathe through his mouth, producing an unnatural condition which kept the mucous membrane of the mouth irritated, and which prevented the cure of the disease. It was easy to cure

after the man was operated on, and his normal breathing restored.

Dr. White says he gives very few drugs. I think it is a good thing to give drugs when it is essential. Several years ago I was a most radical advocate of local treatment, but the more I see of this disease the more I am inclined to enter into the systemic treatment, with the aid of the physician when necessary. Dr. White also speaks of flushing the sewers and getting the patients to drink water—cold water I believe he said. Is that right?

Dr. WHITE. Yes, cold water but not ice-water.

Dr. STEWART. That is a good thing under certain circumstances, but there are other parts of the body to be considered besides the sewer. Nature calls for water when she needs it, and the way to get patients to take large quantities of water is to have them take plenty of exercise. But the thing to be impressed is this: they should not only drink water, but should put their bodies in a condition to call for water. The skin should be stimulated and the blood given free circulation, and then you naturally drink water and in that way flush the sewers, and not only them, but the bloodvessels, arteries, and the veins. I have seen serious systemic disturbances follow the drinking of large quantities of cold water in trying to flush the system. If it be necessary to drink large quantities of water, it should be hot water, as a rule.

Speaking of systemic conditions and systemic treatment reminds me of a case I have reported several times, that of a banker; and, by the way, there were no deposits on these teeth whatsoever, and yet it was one of the worst cases of Riggs' disease I ever saw. How are you going to cure a case of that kind by simple local treatment—by removing the deposits? I treated the case, meeting with fairly good success, and thought I was getting along beautifully, when after a little while I had a reverse; there was a profuse flow of pus that I could not manage at all. The patient was living an indoor life; I tried to scare him into getting out of doors, by telling him that not only his teeth were concerned in the

matter but his entire well-being. He began to take outdoor exercise for two or three hours a day, and I again had fairly good success. However, in the course of two or three months he returned to me with his mouth in possibly a worse condition than it was in the beginning. I tried almost everything I could think of, and at last I put the man on colchicin—something we know very little about. We do not know the effect it has on the system, but we do know that when used empirically it often has a wonderful effect on gouty conditions. That was about five years ago, and that procedure, together with the local treatment, produced a cure, and we have had no further trouble from the case since.

One of the gentlemen sitting near me tonight called to my attention a case that I mentioned before a dental society some time ago. It was the case of a man who had suffered from Riggs' disease for several years, until he became discouraged. He came to me and I began local treatment, but met with very little success. I inquired into his habits, which seemed to be perfect. He was almost a model man—did not smoke, kept regular hours, took a great deal of outdoor exercise, living out in the country—and I could not account for it. He seemed to have no particular ailment, and in obtaining his family history, I questioned him as to his diet, and was told he was very fond of molasses. I asked him how fond he was of it, and he told me he ate it three times a day and a great deal at every meal—that he could not do without it. I suspected that that was the trouble, and I at once cut off the molasses, with but simple treatment, and the man recovered. Dr. Johnson told me shortly afterward that he had heard of many fiendish operations, but he had never before heard of cutting off a man's molasses in order to cure his Riggs' disease.

Dr. WHITE (closing the discussion of his paper). I thank the association very much for the kindly way in which they have received my paper. I am free to confess that I am somewhat of an enthusiast on the subject of pyorrhea, and while Dr. Noel does not agree with me

as to its cure, I still believe nevertheless that it is like many other diseases in that respect. Pyorrhea develops under certain conditions, just as other diseases do; when we change these conditions and treat the patients, we cure the disease. If the patient is negligent and adopts a careless way of living, and drifts back into this same condition—in other words the condition that produced that disease originally—he will naturally have a return of the disease. As I said in my paper, you would not say of a patient coming from a malarial district, that he could not be cured; for if you change the conditions and climate he will be cured, while if he goes back to a malarial district he may have malaria again. So with many other diseases, and this has been my observation with regard to pyorrhea.

As regards Dr. Rhein's radiograph, I think there is possibly a field for it in the study of diagnosis, but I also think that it will have to be developed to a very much greater degree than it is at the present time. I have for a long time hoped that we might have a light of some kind which we could pass immediately back of a tooth, and so locate perfectly the place where the deposits happen to be. It may be that the radiograph will reach that state of perfection where it can be depended upon, but I do not think at present that the radiograph is distinct enough to be of very much value to us in the diagnosis of pyorrhea. There is no question that it is a very valuable adjunct in surgery, and also in dental surgery in locating impacted third molars and unerupted teeth.

Dr. G. V. I. BROWN, Milwaukee, Wis. I am very glad to say that I have seen these cases of Dr. White's, and I want to say that they look better in the mouths than on the screen. Such results as I have seen in Dr. White's office I think I have never met with anywhere else, especially when I have had the opportunity of discussing with the patients the changes that have taken place in their conditions during the course of five, ten, and fifteen years after the treatment. I was glad to have Dr. Allen bring the suggestion to this section along the line

of this paper. It is not a question of how to bring about this lymphatic stimulation, so long as you do bring it about. We have had several papers before the section, and it occurs to me that this is a timely thought that we have our attention directed along that line.

Dr. ALLEN (closing the discussion of his paper). Dr. Crawford misinterprets my ideas, as I never thought of advocating the stimulation or the pounding of inflamed tissues; that I would consider malpractice. I spoke only of stimulating the contiguous tissues. I said common sense, deductive reasoning, and sound pathology would be necessary in order to have good results from this treatment. One who did not know thoroughly what he was doing would get himself and the patient into trouble by the careless or thoughtless application of such methods as I have advocated, and I am glad to make this point clear, that any direct stimulation of diseased tissue is likely to make the condition worse. We want to draw away the serum that results in pressure on the nerve filaments and causes pain, whether an abscess threatens or not. I thank Dr. Finley for emphasizing the fact that where there is pain there is not always necessarily pus. When the adjacent lymphatic glands of any inflamed tissue are stimulated, then unquestionably the inflammation will be affected to the same degree that the glands are stimulated. There is, however, a point beyond which the glands should not be stimulated—a point at which stimulation ceases and irritation begins; and there the questions of common sense and the personal equation of the operator become paramount. I may say that my ideas are yet imperfect, and I hope some day to present clinical examples, and make more clear the ideas that I am now struggling with.

The next order of business as announced by the chairman was the reading of a paper by Dr. E. P. DAMERON, St. Louis, Mo., on "Oral Hygiene in the State Association." Dr. Dameron was not present, and his paper was read by Dr. J. P. Corley. An abstract follows:

ORAL HYGIENE IN THE STATE ASSOCIATION.

The state association is of the greatest importance to the dental surgeon and to the public. To the dental surgeon it is, in a way, a clearing-house, where practitioners from all sections of the state assemble and old and new subjects in dentistry are reviewed. This interchange of thought and the demonstrations of operative and prosthetic work are of undoubted value, and as the dental surgeon is benefited, so in turn is the public benefited. The time is approaching when every active member of the profession will be expected to belong to his state society, and will be looked upon with suspicion by his patients if he does not.

Dentistry as a profession is advancing with rapid strides, and he who fails to keep in touch with his fellow practitioners will soon be left behind by the onward march of progress.

One of the many topics that is receiving much attention is that of the preservation of the health of the teeth and mouth. Endeavoring to learn what work had been done along this line in the past year, programs of state society meetings in fourteen states were examined, and in each of six of these was found at least one paper or clinic—sometimes more—upon the subjects of oral hygiene, prophylaxis, and care of the teeth, being nearly fifty per cent. of those at hand—a very encouraging outlook. Several state associations have a permanent committee on oral hygiene, as should every state, sectional, and national society.

More attention, however, is as yet given to operative and prosthetic technics than to prophylaxis; more to restoration than to prevention, and this condition will probably continue until the thought "clean teeth do not decay" is instilled in every person. Every individual should know that by his own negligence he is subject to inconvenience. A majority of the people of high and low degree are not sufficiently interested in the care of their teeth; oral hygiene is not widely known and fully appreciated by them, but should

it become popularized, instruction would be more sought after than disregarded.

In the advancement of oral hygiene three things in particular are to be overcome: (1) Lack of care in parents or guardians; (2) lack of interest, and perhaps knowledge, on the part of the family physician; (3) lack of instruction and training by the dental surgeon. Indifference, ignorance, and prejudice in parents often prevent the benefits that might be derived by children from proper education in the public schools upon this subject, and yet there is perhaps no better way to overcome these obstacles than by persistent and careful instruction.

Every state society should endeavor to have oral hygiene taught in the public schools of its state. Much good has already resulted from such action. The medical profession has not given the care of the teeth and mouth as much attention as should be given to this subject, but many medical schools have arranged for lectures upon dental topics, so that in the future there may not be so much lack of interest and knowledge by those who enter the practice of medicine. Those already engaged in practice are not to be reached in this way, however, and there could be no better way than that the state dental association memorialize the state medical society, calling special attention to oral hygiene, prophylaxis, and dental pathology.

In a general way most of us have practiced prophylaxis, but systematic care of the teeth and mouth with a view of prevention of their affections has been advocated for comparatively but a few years. As our knowledge of disease increases, the truth of the old saying "an ounce of prevention is better than a pound of cure" becomes more and more apparent. Preventive dentistry is now advocated by many of our progressive dental surgeons, who through prophylactic and hygienic measures have accomplished much toward decreasing, if not preventing, caries of the teeth, in many instances reducing carious action fifty per cent. and reducing the number of other oral ailments to an even greater degree. But there are many engaged in the practice of dentistry who

do not attend society meetings, and seldom, if ever, read a dental journal; thus within the confines of our own profession we find a large field for missionary work. Oral hygiene as advocated today is unknown by many. How then can they give proper instruction and training to those coming to them for treatment? There can be no doubt that it is the province of the state association to look after these indifferent brothers, and for the good of the public supply them with information pertaining to this subject. Many state societies, as already stated, have a standing committee on oral hygiene, but in many instances a "walking delegate" with a "big stick" would be required to spread our gospel.

The general apathy of the public concerning the care of their teeth and mouth is to be deplored, but in a measure is excusable; but apathy in a member of the profession is inexcusable, and cannot be too strongly condemned. While many state societies are endeavoring to spread a knowledge of oral hygiene and the outlook is most favorable, they are somewhat impeded by lack of official literature upon the subject, and it would no doubt be a good plan for the National Dental Association to supply the text of a treatise upon oral hygiene and prophylaxis, which the various state societies could adopt, and urge upon boards of education to adopt as the standard in dental instruction.

To arouse and stimulate interest in this subject among members of the profession, each state association might arrange an essay contest, in charge of the oral hygiene committee, the essayist receiving the highest number of points to be rewarded by a special vote of commendation by the society—or by any plan the society saw fit to adopt. The essential thing is to create interest in oral hygiene in the profession, in the medical profession, in the schools, and in the home.

Articles upon the care of the mouth and teeth are appearing with increasing frequency in many periodicals throughout the country, indicating a growing appreciation of this work.

Section III then adjourned.

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

SUBSCRIPTION PRICES, including postage, \$1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, Canada, and Mexico. To other foreign countries, \$1.75 a year.

Original contributions, society reports, and other correspondence intended for publication should be addressed to the Editor, Lock Box 1615, Philadelphia, Pa.

Subscriptions and communications relating to advertisements should be addressed to the BUSINESS MANAGER of the DENTAL COSMOS, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, MARCH 1907.

EDITORIAL DEPARTMENT.

THE CODE OF ETHICS.

THE time seems to be ripe, or at least it is ripening, when it might be desirable to seriously examine our code of ethics. We have a code, to be sure: occasional reference is made to it in the routine transaction of society business; a standing rule of the National Association makes it necessary that every society sending delegates to the national body shall subscribe to and maintain the provisions of the code; once in a while the code is published; nearly every practitioner has heard about it, but not one in a hundred, we venture to state, has ever read it carefully and thoughtfully. We would go farther and express the belief that but few relatively have any clear concrete idea concerning the meaning of professional ethics, or even so much thereof as the code embodies.

We are of this belief because "ethics" and "ethical" are terms which have suffered much the same sort of maltreatment that has been visited upon the terms "science" and "scientific."

We have the science of whitewashing, of pugilism, of base-ball, of bridge whist, of tight-rope walking, fly-fishing, golf, and target shooting. We have Christian science, so called, possibly on the same principle that we call ferrous sulfate copperas—doubtless because it contains no copper. So by the same type of inverted logic we have ethical dentifrices, ethical anesthetic agents, ethical nostrums and appliances, from a whirling spray to a cervix clamp, which one may purchase *ad libitum*. All of which indicates that it is high time to take our code of ethics out of the archives, dust it off a bit, and see whether it really is a code of ethics, and how fully it measures up to the needs of this later generation of practitioners that is making such liberal interpretations of the term ethics and giving it such a variety of novel applications.

Ethics in its broad sense being the science of right conduct and right character, then dental ethics becomes merely the application of this doctrine to the special case of dental professional relations. Unfortunately our code has attempted to deal only with the conduct and character of the dentist in the strictly professional sense as a professional or business man, and not as a human being, a social unit incidentally practicing dentistry. It has apparently taken for granted, for the most part, that the ethical considerations which should in general govern a man's relations to his fellow men need not be repeated in the professional code. This omission we deem to be unfortunate. Why, if the code is to serve as the standard of ethics in dentistry, should it not be more comprehensive in its specifications, if it is to contain any specifications at all? It is true that the code distinctly states that "The person and office arrangements of the dentist should indicate that he is a gentleman, and he should maintain a high-toned moral character"—which is indeed the essence of the whole matter, for on this commandment hang all the other articles of the code. But in view of the multiplicity of conceptions as to what constitutes a gentleman, the framers of the code evidently believed it to be necessary to particularize a few instances of misconduct which fall under the ban of unprofessionalism, and it is curious to note that nearly every one of these particular specifications has a bearing more or less direct upon the monetary aspect of professional work.

It is pronounced by the code to be unprofessional to resort to public advertisements calling attention to peculiar styles of work, prices for services, or special modes of operating, or to claim superiority over neighboring practitioners, to publish reports of cases or certificates in the public prints, to go from house to house soliciting or performing operations, to circulate or recommend nostrums, or to perform any other similar acts. The next following section of the code provides that no dentist shall do any act that will tend to take a patient away from a colleague; and the concluding section of Article II provides for the maintenance of the standard fee bill agreed upon by practitioners of a given locality. The other articles of the code are general in the character of their provisions.

The two features of the code which we regard as being open to criticism are its failure to include definite specifications as to the foundation principles that go toward the making of professional character, and the undue emphasis that is particularly placed upon that type of wrong-doing which is an offense because it strikes at the pocket-book rather than at the character of a colleague. We are of opinion that the code should be amplified and made more specific upon the several ethical points with which it deals. We are of that opinion because, notwithstanding the fact that over nineteen centuries have elapsed since the enunciation of the ethical principles which we claim to accept as the basis of our civilization, it is nevertheless true that those same principles which we pronounce so trippingly on the tongue are not even yet the true coefficients of our social order; and it thus remains also true that the greatest sympathetic nerve of the human organism has its deep origin in the pocket-book.

One cannot fail to note the emphasis which the code gives to all misdemeanors involving the filching of his neighbor's business, and its lack of emphasis upon all matters relating to the filching of his character. With the former wrong it deals specifically and at length; the latter it dismisses with glittering generalities. If the code simply required that a dentist should be a gentleman and live up to the standard of the golden rule it would have amply covered the ground; but in its attempt to paint the lily, to improve on the most comprehensive ethical precept given to man, it has muddled the case badly by entering

into particulars, choosing as the most important for specification those acts of unprofessionalism growing out of individual greed for the property or material possessions of another, while referring only indirectly to all other and more important ethical considerations by requiring that the person and office arrangements of the dentist should indicate that he is a gentleman. Would it not be as well for the code to practically recognize the professional importance and applicability of the ethical principle laid down in the command "Thou shalt not bear false witness against thy neighbor" as it is to enforce the command "Thou shalt not steal"? It is true that the code provides that a dentist's person and his office arrangements should indicate that he is a gentleman, but why treat the point involved in such a stepmotherly manner? Why not say that a dentist's acts as well as his professional surroundings should demonstrate that he is a gentleman. Surely there is abundant need for the propagation of a larger meaning for the phrase "professional ethics," and something more definite should be done to emphasize the importance in everyday professional life of the principle set forth in the ninth commandment of the Mosaic code.

To those who know and appreciate the full force and meaning of the word *gentleman*, and live up to that standard, no other code of ethics is needed; but unfortunately the spirit of the Pharisee is still in evidence, and for the ethical control of that spirit in humanity, even in professional humanity, a specific code is necessary—one that deals not only with principles but which particularizes the application of those principles.

For these reasons we regard our present code of ethics as imperfect because it fails to reach the real sources of professional wrong-doing, and because it is concerned mainly with protecting the material business interests of the profession while neglecting the conservation of professional character individually and collectively.

REVIEW OF CURRENT DENTAL LITERATURE.

Conducted by JULIO ENDELMAN, D.D.S.

[*Schweizerische Vierteljahrsschrift für Zahnheilkunde*, Zürich, January 1907.]

ON CERTAIN SPECIAL FORMS OF NECROSIS OF THE MAXILLÆ. BY DR. MAURICE ROY, PROFESSOR AT THE ÉCOLE DENTAIRE OF PARIS, DENTIST OF THE HOSPITALS, ETC.

The type of osteitis which leads to necrosis of the maxillæ may be due to various causes, among which those of dental origin are the most frequently encountered. Osteitis of the jaws of purely dental origin evolves in ways which vary according to the character of the tissues in which it arises, and of the causative microbic elements. The author reports in detail three cases of maxillary necrosis as representing three different types of the disturbance under consideration. The first case was that of a man, thirty-nine years of age, of excellent clinical history, whose teeth—both upper and lower—were free from caries. The onset of the disturbance was marked by the discharge of pus through a fistula, the outlet of which was situated below the lingual surface of the crown of the lower left first bicuspid. The concealed abscess had to all appearances healed about twenty-four hours after the beginning of the discharge, but it had cut short the life of the tooth, which was found to be very loose and surrounded by inflamed and receded gum tissue. The same condition of things repeated itself in the case of every tooth on each side of the bicuspid, and eventually caused the shedding of the teeth from the lower left third molar to the lower right second bicuspid inclusive. All possible efforts on the part of Dr. Roy and associates—efforts therapeutic and surgical—were of no avail in averting the trouble, which came to a halt following a rheumatic periostitis of the ascending mandibular ramus. The history of the case is peculiar on several accounts, and

its etiology rather obscure, as there were no carious cavities in any of the affected teeth, and also because any other plausible cause of maxillary necrosis—including actinomycosis—could not be detected. The patient was of the rheumatic diathesis, and in view of the occurrence of a rheumatic periostitis and of an attack of general rheumatism—the latter coincident with the onset of the disturbance—a diagnosis of rheumatic osteitis of the mandible was reached. It is noteworthy that while the usual oral manifestations of rheumatism are in the form of pyorrhea alveolaris, recession of the gum, alveolar resorption, loosening of the teeth, and occasionally small sequestra, in the case under consideration the teeth themselves were not affected, as the entire series of pathologic phenomena was localized in the mandible and alveolar ridge.

The second case was that of a man twenty-four years of age, who had been suffering for some time from abscesses in the maxillæ, and, more recently, from nasal suppuration. An examination of the mouth showed that the mucous membrane above the incisors and canines was violaceous, and revealed the presence of two small fistulæ above the lateral incisors. All the upper teeth were of healthy appearance, although the incisors and canines—especially the central incisors—were movable. The teeth were of uniform grayish color, and consequently it was difficult to ascertain the condition of the pulps of the affected teeth. There was no history of traumatism. An explorer introduced into the fistulous tracts was found to penetrate into soft, spongy tissue. The exploring operation was followed by slight hemorrhage from the mouth and nose, and a second examination showed that the mobility of the teeth was due to the mobility of the surrounding bone area. The gingival mucous membrane was of normal appearance and closely ad-

herent to the necks of the teeth. The disturbance had been going on for several months, and during all of this time had not given rise to any painful sensations, the patient, as a matter of fact, being discomforted only by the persistent and ever-increasing suppuration.

The progress of the disease and its general aspect pointed at once to a diagnosis of tuberculous necrosis, particularly in view of the fact that the general appearance of the patient, as well as his antecedents, tended to corroborate this diagnosis. A general examination of the patient confirmed the diagnosis in so far as it brought out the existence of pulmonary lesions. The foregoing data, and in addition the caseous character of the bone, made it possible to confirm the diagnosis. In view of the absence of carious cavities—the ordinary avenue of penetration of the tubercle bacillus—it is not perhaps unreasonable to suppose that the tuberculous osteitis of the mandible had originated in an intranasal infection. The patient was successfully operated upon, and while both the general and local condition improved steadily, the general tuberculous infection eventually carried him off about five years after the operation.

The third case reported by Dr. Roy was that of a man twenty-six years of age, in whom the infection of the pericementum of a lower left bicuspid spread to the periosteum of the jaw with such an intensity as to bring about in several days the necrosis *en masse* of almost the entire osseous area, from the lower left first molar to the canine of the same side. Nothing in the general condition of the patient was found that could have been considered as a factor in the etiology of the lesion, which as above stated, was the outcome of the invasion of the maxillary periosteum by some virulent forms of microorganisms.

[*La Revue de Stomatologie*, Paris, November 1906.]

ON A RARE COMPLICATION OF PYORRHEA ALVEOLARIS. BY DR. V. GALIPPE.

The author relates the case of an aged patient, of pale and waxy complexion, who for a long time past had been suffering from chronic enteritis. At the time of the exami-

nation by Dr. Galippe, he was just recovering from an attack of the grippe, and presented in addition to an intense pharyngitis and a pyorrheal condition, a peculiar form of gingivo-stomatitis, which has not been thus far reported or observed. Around the teeth, and in particular at the level of the upper left second molar, were a number of opal-colored plaques, easily detachable and reproducing themselves by auto-inoculation from the upper to the lower jaw. At first, judging from the general condition of the patient, the author believed that the disturbance was of the nature of a superficial sphacelus. There was absence of fever, and when the membranous plaques were removed the underlying mucous membranes appeared, although intensely red, by no means deeply ulcerated.

The antiseptic treatment which was instituted was not followed by the rapid improvement which had been anticipated, and the membranous plaques continued to grow and multiply, although the newly formed ones were smaller and fewer. In view of these developments the original diagnosis had to be modified, and in order to obtain a clearer view of the case Dr. Galippe requested Dr. Malassez to examine the false membranes, which he himself thought at first to have been constituted by the buccal mucous membrane. After repeated examinations Dr. Malassez reported that the membranes were composed exclusively of white blood corpuscles, and that they contained no connective tissue, vessels, or glands. At different areas of each membrane microbic agglomerations could be seen, but the exact nature of the microbes could not be detected through the microscopic examinations alone. It was not the mucous membrane that had undergone a necrobiotic process, neither were there eschars, as are usually formed consequent upon inflammatory disorders of microbic origin in the mucous membrane of these regions. The plaques were precisely of the nature of false membranes.

In the meantime the patient left the city on an extended trip, and upon his return, conditions had so far improved that a painstaking bacteriological examination by Vincent, the well-known authority on the bacteria of the oral cavity, resulted in the isolation of the pyogenic cocci and of a non-pathogenic anaerobic bacillus. The author of this re-

port considers it advisable to record this observation, notwithstanding the regrettable fact that the true cause of the production of the membranes still remains unknown. It may at least serve the purpose of preventing an erroneous diagnosis should similar cases occur in the future.

[*Semaine Médicale*, Paris, July 18, 1906.]

COCAINIZATION OF THE INFERIOR DENTAL NERVE FOR THE PAINLESS EXTRACTION OF MANDIBULAR TEETH. BY DR. NOGUÉ.

The author anesthetizes the inferior dental nerve by the method described in the recent thesis of Dr. Pageix. The injection may be performed by means of a Pravaz syringe and the ordinary hypodermic needle, but it is advisable to employ a cannula of about 7 cm. in length, bent to a bayonet shape, and provided at its free end with a needle of about 1½ cm. in length, in lieu of the hypodermic needle of regulation size and form. The point of election for the injection is ascertained by introducing the index finger into the mouth, and carrying it as far as the anterior border of the ascending ramus, when by slightly moving it toward the opposite side of the jaw, it will encounter a ligament offering a high degree of resistance to any effort to displace it. This ligamentous structure is the internal pterygoid muscle, and in the groove between it and the internal surface of the ramus is found the path of the inferior dental vessels and nerves. The needle should be introduced at a point as close as possible to the osseous structure of the jaw, and from 1 to 2 cm. of a 1 per cent. solution of cocain hydrochlorid injected into the tissues.

At first but a portion of the solution is injected, the remainder being expelled from the syringe after carefully moving the latter toward the labial commissure of the opposite side, in order to thus bring the point of the needle in closer proximity to the nerve trunk. From three to six minutes after the introduction of the injection the patient experiences a feeling of formication on the corresponding side of the lip and jaw, and shortly afterward the entire region which has been the seat of the formication becomes absolutely anesthetized, and remains so for an interval of about twenty minutes.

The failures which have been observed with

the method under consideration—about one-third of the cases in which it has been used—have been due, in the opinion of the author, to an imperfect technique, and the only accident that has been recorded up to date was a temporary contraction of the muscles of mastication, caused by the puncturing of the internal pterygoid muscle with the needle.

[*Deutsche Zahnärztliche Wochenschrift*, Berlin, August 11, 1906.]

ECZEMA OF THE LIP AND THE RÔLE OF CERTAIN MOUTH-WASHES IN ITS ETIOLOGY. BY ALBERT REISSNER, MUNICH.

Ecze-ma, in the etiology of which the ingredients of mouth-washes play an important rôle, is not so rarely met with as Galewsky of Dresden is inclined to believe. The author has observed eighty cases of lip eczema, and reports upon them, especially in their bearing upon the central subject of his investigations, namely, the rôle which certain mouth-washes may play in bringing about the disorder.

It occurs with greater frequency in the autumn months, particularly in women of very thin skin, who are liable to suffer from cracked or fissured lips. In almost all cases the onset of the disturbance is marked by redness and swelling of the lower lip—extending quite frequently to the labial commissure—and by pain and a sensation of tension. As in all cases of eczema, desquamation soon follows. Galewsky mentions fissures of the lip as one of the symptoms of labial eczema, whereas in Mr. Reissner's opinion they are but a predisposing cause—one of the avenues through which penetrate the irritating agents that produce hyperemia, the migration of the white corpuscles, and the edema of the tissues.

Certain mouth-washes have been said to act as the irritating agent in cases of lip eczema, particularly those which contain salol among other ingredients. He has investigated the subject by experimenting with a number of preparations, and has found that a mixture of alcohol with a few crystals of salol never acts as the irritating agent in eczema, but that the use of a solution in which oil of peppermint is present—in the proportion of twenty-five drops of the oil to about three and one-third ounces of the salol

solution—is followed by abnormal manifestations in the lips, which cannot be differentiated from the characteristic signs of the first stages of eczema. In addition, by further investigation of the subject, he was led to frame the conclusion that all essential oils under similar conditions, will cause similar phenomena about the mucous membranes of the lips and adjacent structures.

The only method of treatment suggested by the author is the one which consists in eliminating the source of irritation, and in the frequent external application of ice. The application of soothing ointments Mr. Reissner considers as unnecessary.

[*La Revue de Stomatologie*, Paris, November 1906.]

INTRADENTAL ANESTHESIA BY MEANS OF EXTRA-DENTAL INJECTIONS OF COCAIN-ADRENALIN. By DR. CROS, BÉZIERES, FRANCE.

The author has devoted considerable time to the study of the question of abolishing as much as possible the pain which in the large majority of cases accompanies the performance of dental operations. The therapeutic problem of rendering painless the curetting of the dentin he has carefully investigated, and in view of the difficulties accompanying the topical application of obtundents, often of but mediocre value in so far as their effects are concerned, has had recourse to a method which has given him most satisfactory results, and which he outlines as follows:

He injects into the tissues overlying the tooth to be operated upon from 3 to 4 cm. of a one per cent. solution of cocain hydrochlorid, to which one, or in some cases two, drops of adrenalin chlorid solution are added. The injection is performed as for the extraction of teeth, with the slight difference in technique that instead of waiting only three or four minutes before operating, Dr. Cros postpones operating until eight or ten minutes have elapsed from the time the injection is made. The results which he has obtained have thus far been so encouraging that at the present time he employs the method extensively in cases of caries of the second degree, pulpitis, etc., and to prevent the pain caused by the cutting of the crown of a live tooth preparatory to crowning. Cervical cavities

of the second degree, invariably so painful to excavate, especially in young patients, may be prepared by the method in question without causing any disagreeable sensation, and if any overhanging gum-margin be found crowded into the cavity, it may be removed without any discomfort whatever.

The author concludes his article with a report of several cases in which the extra-dental injection of the cocain-adrenalin solution had permitted him to perform painlessly operations which otherwise would have been the source of intense discomfort.

[*Le Laboratoire*, Paris, January 6, 1907.]
THE WORK OF JOSEPH AUDIBRAN. By B. PLATSCHICK.

Even before the application of porcelain to dental art had been completely generalized or accepted without discussion by the majority of dentists, spirited polemics had already arisen regarding the priority of its invention. Public opinion became divided, owing to an echoing lawsuit between Duchateau and Dubois de Chemant, each of whom pretended to be the inventor. Duchateau had the support of his implacable followers, while Dubois de Chemant was none the less fortunate in this respect.

The discussion regarding the priority of the invention assumed such large proportions that it led to the publication of works on the subject by Duchateau and Dubois de Chemant respectively, in which each endeavored to establish his rights to the claim of being the inventor of the method of making mineral teeth, and to invalidate those of his adversary. The discussion was also taken up by some of the contemporaneous writers, and especially by J. Audibran, who devotes an entire chapter to the subject in his "Historical and Practical Treatise on the Incorruptible Artificial Teeth: Containing the Methods of Manufacture and Application. Work approved by the Society of Medicine. Paris, 1821." According to Audibran, the sole inventor is the apothecary of Saint-Germain—Duchateau—while Dubois de Chemant is but a vulgar usurper. But in order to record the facts as accurately as possible, it must be said that the invention belongs not even to Duchateau, for it can be traced back to the founder of the dental art, to the inspirer of all dentists, to the genial Fauchard, who it

will be remembered, in Chapter XIX of his treatise, speaks of the "enameling of dentures made of hippopotamus or elephant ivory to replace and imitate the natural structure—for while the natural eyes have been imitated with eyes composed of enamel, we have neglected the application of this art to the making of artificial dentures." Even in the absence of any other allusion by Fauchard, that remark would be ample justification for the claim which gives to him the priority of the invention. However, according to Audibran, Fauchard did not stop there, for while he does not specifically refer to "porcelain teeth," it is evident that he employed in the preparation of his fictitious enamel ingredients such as might be employed in the manufacture of artificial teeth. Consequently it would not be unreasonable to suppose or assume that he was the first to employ porcelain paste in the manufacture of the "body" of artificial teeth.

"It is therefore possible," says Audibran, "to justly reclaim for this dentist the merits of priority, or at least those of having suggested the primitive idea that led to the invention of incorruptible teeth." Audibran gives in addition some valuable information concerning one Guillemeau, who seems to have been the originator of a paste for making artificial teeth "which never became yellow." He published his formula, which is as follows: "Take some pure white wax melted with a small amount of gum, and add to it a powder consisting of white mastic, coral, and mother of pearl." Audibran believes that Guillemeau, through his published formula, inspired the idea of manufacturing artificial teeth of porcelain paste. "It is possible," says Platschick, "to admit the plausibility of the foregoing statements concerning Guillemeau, but the difficulty lies in the fact that none of Guillemeau's contemporaneous authors have ever mentioned him in this or any other connection." Audibran does not seem to have the slightest doubt that Fauchard, having practiced his profession during a period of thirty years after the publication of his treatise, and having been impressed during that time with the disadvantages of using putrescible substances, did not limit himself to the manufacture of enamels. He must have profited by the beautiful experiments of Réaumur, which eventually made

possible the founding of the royal manufactory of porcelain of Sevres. Fauchard's ideas of the advantages of the porcelain paste in the manufacture of complete dentures probably led him to experiment with porcelain. It is likewise possible that the discovery by Fannay, in 1740, of the manner of applying the red color on porcelain, might have suggested to Fauchard the idea of making dentures with artificial gums.

Regarding the relation of Dubois de Chemant and Duchateau to the introduction of mineral teeth, it should be remembered that Duchateau, the apothecary of Saint-Germain-en-Laye, having worn a denture made of hippopotamus ivory, had personally experienced the disadvantages, from a hygienic point of view, of such a denture, and had on that account been led, in 1774, to construct a denture of porcelain. To carry out his plans he sought the assistance of the manufacturing establishment of which a Mr. Guerrard was the proprietor. The work having succeeded beyond all expectations, Duchateau communicated his invention to the Academy of Surgery in 1776. Unfortunately, however, the tests subsequently made were not followed by the same successful results, and gradually the invention was lost sight of. In 1778 a dentist of Paris, by the name of Nicolas Dubois de Chemant, entered into an agreement with Duchateau by virtue of which he was to acquire the secret of the latter's invention. Once in possession of the secret, Dubois de Chemant, as expressed by Audibran, "blew all the trumpets of fame to announce his new teeth of mineral paste," which he for the first time designated under the term "incorruptible." He published a pamphlet in 1789 under the title of "Dissertation on the Advantages of the New Teeth and Dentures without Odor," which is remarkable on account of the emphatic way in which it condemns all the materials employed by his professional contemporaries.

Notwithstanding the shrewd advertising of Dubois de Chemant in favor of the invention, his success was only mediocre, on account of the crudeness of his attempts to imitate natural conditions. Having failed in so far as public favor was concerned, he addressed himself to the Academy of Surgery, where he likewise failed in securing the support he was in vain seeking everywhere, for the re-

port of the commissioners of the Academy, Dubois-Foucou and Sue—father of the celebrated writer Eugene Sue—was unfavorable to him and his professional interests. However, his claims were favored by the Royal Society of Medicine, and by its action he was enabled to secure a patent for a period of fifteen years. It was at this time that Duchateau carried the case before the courts of the land, for among other things Dubois de Chemant had failed to comply with the article of the agreement in which he pledged himself not to divulge the secret of the process of manufacture of artificial teeth invented by Duchateau. A patent being an irrevocable document, and having been so declared by the court before which the case was tried, Duchateau lost his case, and Dubois de Chemant, although unjustly, still remained before the eyes of the public as the inventor of something he had never originated. Shortly afterward Dubois de Chemant secured a patent in England which protected his invention for a period of twelve years.

Dubois-Foucou, on the other hand, seized the porcelain idea; carried on investigations with the view to correct imperfections; worked indefatigably, and eventually succeeded. At first he employed hard porcelain, but being unable to attain in his furnace the temperature at which it fuses, he turned his attention to the soft porcelain of Sèvres. This paste not being sufficiently resistant to withstand the action of the secretions of the mouth, he eventually devised an improved formula, containing clay of Limoges (kaolin), amber earth, Belleville sand, terre de Renard, manganese, cobalt, and petunse. With these different substances he produced artificial teeth of the three principal colors—

bluish black, grayish white, and yellowish white.

Although Audibran speaks of the first usurper, Dubois de Chemant, in a tone of deep indignation, yet of the second usurper, Dubois-Foucou, he speaks in more moderate terms and in a tone of indulgence; for, in his—as it seems to us—authoritative opinion, while Duchateau is the true inventor of dental porcelain, Dubois-Foucou was the first to publish and improve the invention.

But Dubois de Chemant and Dubois-Foucou were by no means the only ones who attempted to appropriate Duchateau's invention. In 1808 Fonzi announced a new improvement in porcelain teeth, consisting in that each tooth was made separately (individual porcelain teeth) and provided with platinum pins. These new teeth he presented at the *Athénée des Arts*, which society awarded him a medal and a wreath.

Audibran does not question the merits of Fonzi's invention, but accuses him—*le Sieur Fonzi, dentiste étranger*—of accepting honors and rewards which should have been awarded to the real inventor and his successors.

In 1812 Dubois-Foucou anonymously created a fund for the striking of a suitable medal to be awarded to the author of the answers to five questions concerning the improvement of artificial teeth. Two memoirs were presented by Maggiolo of Nancy and Cornelio of Turin, and one by Audibran in the form of the treatise referred to in the text of the present review. Maggiolo received an honorable mention, and as nothing can be found regarding Audibran's literary efforts, it would seem that his work was entirely ignored.

PERISCOPE.

Opening Flasks.—The fit of a great many rubber plates has been spoiled by opening the flask too soon after vulcanization. It should be thoroughly cooled before the flask bolts are removed, or warping is nearly certain to take place.—*Western Dental Journal*.

Treatment of Sensitive Cervical Margins.—If sodium bicarbonate is incorporated in the tooth-powder used by the patient, sensitiveness will be relieved, and he will be enabled to thoroughly masticate, thus bringing about a normal condition of the saliva.—D. SPALDING, *Dental Register*.

Pain After Tooth-Extraction.—The extraction of an abscessed tooth is generally followed by great pain. I have found lysol to be the ideal remedy in such conditions, placing it undiluted in the socket. It will relieve the pain immediately, help to check the hemorrhage, and establish antiseptic conditions in the socket.—G. B. WINTER, *Dental Era*.

An Important Physiological Requirement in Pulp-Capping.—In order to encourage the throwing out of secondary dentin as a protective to the pulp, the greatest care must be used to preserve the superficial soft-tissue layer of the pulp, from which the secondary dentin is formed, much in the same way as a surgeon preserves the periosteum intact for future bone-formation.—F. COLEMAN, *Dental Record*.

Attaching Facings to Caps with Porcelain.—Make the cap of platinum soldered with pure gold. The post should be of platinum or iridio-platinum. Let the facing end of the post extend one-quarter of an inch beyond the cap, and take an impression with the cap and post in position on the root. Take a bite if necessary. Set the cap and post in the impression and run a cast of investment compound. Grind a facing to fit the cap and bend the pins upward and out of the way, but closely in contact with the protruding end of the post. Cut off the end of the post, leaving enough to be reached by pins. Invest and attach the post to the pins and cap with a little pure gold. Remove the

investment and add the porcelain body. The first baking should not extend higher than the pins, or the contraction upon cooling might check the facing. This makes a little stronger crown than where the facing is backed and soldered to the cap, is but little more trouble, and costs less.—R. E. SPARKS, *Dental Review*.

Glycerin and Rose-water.—A bottle of glycerin diluted to half strength with rose-water should be kept on hand constantly to apply to the patient's lips before operating, as it overcomes any tendency to soreness. Smear over the holes in the rubber dam it facilitates passage between the teeth, and is much less objectionable than soap or vaselin.—*Dental Review*.

The Necessity for Dental Services in Public Institutions.—There should be a dentist on every hospital staff, on the medical staff of every home for the orphan or the aged, and on the staff of every other public or eleemosynary institution. I will go farther, and state that every institution that requires a physician should also have a dentist.—F. W. WISEMAN, *Dental Era*.

A Gold Corner on a Porcelain Facing.—Grind off the corner and burnish the backing over the spot; remove, invest, and solder on the gold corner. Polish and replace on the porcelain. By this method a diamond drill is not required. The gold corner on the inlay is admissible only in a mouth where other teeth are already contoured with gold.—L. A. STEMLER, *Items of Interest*.

Death Caused by the Swallowing of an Artificial Denture.—The *News and Observer* of Raleigh, N. C., the leading daily paper of that city, reports on January 29th the case of a lady patient in the Watts Hospital of Raleigh, who was convalescing from an operation to which she had submitted three weeks previously, and had recovered rapidly to the point where she was considered to be entirely out of danger. She had been seen by her physician, who had just left her, when he was recalled from another ward by the nurse, and hurried to the patient's bedside to find

that she was manifesting evidences of strangulation.

Suspecting that she might possibly have swallowed her artificial teeth, an examination was made, and the artificial fixture was found to be located in the patient's throat. The plate was removed as quickly as possible, but life was then extinct. The physician said that she had either strangled to death or ruptured a bloodvessel in her effort to remove the plate. The small plate fitted flatly over the windpipe. But a few minutes elapsed between the time when the doctor left her and her death.

Investing Crowns and Bridges.—Indifference and slovenly methods used in investing crowns and bridges produce too frequently unsatisfactorily fitting bridges, and result in broken and checked facings. The habit of pushing a case into a soft, moving mass of investment, which in turn rests on an uneven or soft surface, such as blotting paper, or even common paper, is bad practice. Proper size boxes, from the ordinary sandpaper disk boxes to well-selected ones of larger sizes, should be used. The boxes filled about two-thirds with investment material will firmly hold and securely incase every line and crevice of the invested bridge or crown. Save your sandpaper disk boxes; they are useful when investing a single crown or small bridges.—A. PERCIVAL BURKHART, *Items of Interest*.

Setting Crowns and Bridges with Gutta-percha Cement.—During many years the cementation of crowns and bridges has been with me a subject of close study, and many, many times I have wished I might with ease remove a crown or bridge. One of the causes I may say was, for instance, this complaint: "Doctor, that bridge you set in my mouth bothers me, because one or two of the abutments ache at times, and are sensitive to heat and cold"; or the patient has reported a cap on an abutment loose, while the others remained perfectly firm. To remove a bridge under such conditions—and yet safety and duty suggest it—means tremendous labor, particularly if it include one or more Richmond crowns. The conditions mentioned have confronted nearly every dentist, whether of limited or extensive experience. Many valuable abutments are destroyed because of the difficulty attending the timely removal of bridges set with crystal cements. So far as single crowns on anterior roots are concerned, for years I have employed gutta-percha, and with most excellent results; but for bridges, up to about three years ago, I continued using the ordinary crystal cements. Three years

ago I began using Evans' gutta-percha cement for setting bridges, using it cautiously at first, but now I use it almost exclusively. As a result of my observation and experience, I now find myself in a position to remove a bridge easily and quickly without injury to an abutment. I make it a rule to instruct my patients to return for an examination twice each year, and if dangerous symptoms should be present, I remove the bridge and perform such services as will best benefit the case. Had I used gutta-percha cement earlier in my practice, and observed the rules I now do, I am sure numerous valuable abutments which were lost would now be in a good state of preservation.—A. PERCIVAL BURKHART, *Items of Interest*.

Packing and Finishing of Cement Fillings.—While matrices and a previous separation may be of value in making some fillings which should be given a buckling point of contact, clinical evidence indicates that a cement filling in any occluso-approximal cavity should have a much larger contact surface presented to the adjoining tooth. The cement should be packed firmly directly against the approximal surface of the adjoining tooth, and in finishing, an interdental space created at the cervical third only. By dismissing the case in this condition, floss silk can be carried through to the cervical space and withdrawn laterally after a few hours, and the history will be that food will not be forced against the gum septa for a series of years, provided the cement was mixed to the proper degree of stiffness.—W. V.B. AMES, *Dental Era*.

Prosthetic Hints.—A good pickling outfit can be made by taking a large-size cigar box; fill it two-thirds full of plaster, mixed fairly thin, and while it is still soft set in it three common crockery cups. When the plaster is set, these can be removed and cleaned, and when in their place cannot be tipped over. One is for the acid, the next for sodium bicarbonate solution, and the third for plain water; the cover of the box keeps everything clean.

A stock solution of whiting or yellow ocher in alcohol is handy to coat the surfaces upon which you do not wish the solder to flow. This same solution is useful as a separator for Melotte's metal dies. Vaseline on strips and disks prevents them from catching in the rubber dam, and they will not become hot. If saved, they will eventually bring a few easy dollars from the refiner.—*Pacific Dental Gazette*.

Expansion of Plaster of Paris Casts and its Compensation by the Contraction of Zinc Dies.—The expansion of plaster can be readily perceived by anyone who is called upon to employ this material in the laboratory. I will give you a little of my personal experience. Out of seven plaster impressions taken of five different mouths, dies made of low-fusing metal resulted in five misfits. Of five plaster impressions of the same five mouths—taken as most of us take these plaster impressions—zinc dies made from those plaster casts resulted in five fits; that is to say, the patients could wear the plates constructed upon these dies. We all know that zinc shrinks considerably, and the shrinkage of the zinc just about compensated for the expansion of the plaster.—*Dental Register*.

The Reliability of Amalgam.—During the past ten years, and a little over, I have kept up my work with this material, and during that time I can say that I know of many fillings that have been made by myself and others that have kept as clean margins, just as free from any discoloration of the dentin or enamel, as have any gold fillings, and believe this may be made general. I do not claim that this can be done with the same regularity as can be done with gold; nor that it is as easy to do this in any ordinary method of working with amalgam—the manipulation of amalgam to produce regularly first-class results is more difficult than the manipulation of gold, therefore it is in that degree a less reliable material—but that the operations with amalgam which you perform for your patients can be improved, and vastly improved, I feel confident, without any possibility of doubt.—G. V. BLACK, *Dental Practice*.

A Comparison of the Properties of Novocain and Alypin with those of Cocain.—In the *Répertoire de Pharmacie* of September 10th and October 10th, M. Paul Lemaire has given a useful comparison of the properties of novocain and alypin with those of cocain. These substitutes for cocain are considered to possess similar physiological properties to cocain, and it is claimed for them that they possess the additional advantage of withstanding sterilization at the boiling-point or at 110° C. in an autoclave, without impairment of their anesthetic properties. Aqueous solutions of both novocain and alypin have a neutral reaction, and they are both precipitated by the usual alkaloidal reagents and by ammonia, caustic soda, lead subacetate, and silver nitrate. Alypin, like cocain hydrochlorid and stovain, is precipitated by sodium

carbonate and by borax, but novocain is compatible with these substances and with potassium iodid. Hence it can be prescribed in the form of eye-drops containing novocain gm. 0.1, borax gm. 0.2, and distilled water gm. 10; as a subconjunctival injection containing novocain gm. 0.25, potassium iodid gm. 0.5, and distilled water sufficient to make 10 ccm. If a solution of novocain acquires a yellow color it should be rejected, as it may then cause irritation.—*Dental Record*.

Splints for the Anterior Lower Teeth.—A few years ago a very good-looking young woman, whose lower incisors I had previously treated for pyorrhea, returned to me with the gums very much receded, and two of the teeth so loose that I feared their loss very soon. It was a "condition, and not a theory," and demanded prompt and definite action. The teeth were white, rather long, thin, regular, and much in evidence when talking. To employ bands or other appliances showing gold seemed out of the question. As a temporary brace, the teeth were tied together with silk ligature down close to the gum. Then a model was obtained from a plaster impression, and from this a metal die was made. To the lingual surface of each tooth a piece of pure gold was swaged from the cutting edge to just below the thickest portion of the tooth at its base. Perpendicular holes were drilled in each tooth, one at the base, and one, and sometimes two, at or near the top. The gold backings were then placed on the teeth and punctured to conform to the drilled holes. A good method of holding them to their positions is to tie them with a silk ligature.

A platino-iridium wire of suitable gage and preferably threaded is placed in each hole, and allowed to extend above the backing from one-eighth to one-fourth of an inch. Plaster is then flowed over the pins and backing for the purpose of removing them intact. The portion of the pin extending above the backing should be flattened on one side, or beveled at the end, as a guide in readjusting it, in case it pulls or is displaced in removing. The pins are then soldered to the backing, using but little solder. The backing is then replaced on the tooth and carefully burnished to place. Remove, and invest the backing and reinforce with solder. Now replace them on the teeth, remove in a plaster impression, invest, and solder them together. It is advisable to adjust the rubber dam before cementing the piece in place. I have set several splints constructed in this manner, and as I have seen them from time to time since, they were apparently holding perfectly.—R. I. BLAKEMAN, *Dental Summary*.

[The method of splinting teeth loosened by

pyorrhea, above outlined by Dr. Blakeman, is practically identical to the procedure described by Dr. W. V-B. Ames, and published in the report of the Transactions of the National Dental Association for 1901, and in the DENTAL COSMOS for May 1903, in a paper entitled "Bridge Work in the Cure of Pyorrhea Alveolaris." Dr. Blakeman makes no allusion to the devitalization of the loose teeth to be splinted; while Dr. Ames for reasons sufficiently warrantable, and in accord with the opinion of an array of clinicians and special investigators, advocates and practices the devitalization of the diseased organs in all cases in which the retention calls for radical procedure.—Ed.]

Prescription for Obtunding Sensitive Dentin.—

R—Menthol,	gr. xx;
Chloroformi,	℥ss;
Etheris,	℥3j. F.

Sig.—Use as directed.

This will not completely desensitize all dentin, but in large cavities where there is an extensive area involved, and where the dentin is extremely sensitive, take a little pellet of cotton, saturate it with the above liquid, place it in the cavity after the rubber dam has been adjusted, and you will find by the time you are ready to excavate the dentin that the ether and chloroform have volatilized. The value of this remedy depends largely upon the volatilization of these fluids. As the two liquids are volatilized there is abstracted from the tooth-structures a certain amount of heat, and that volatilization drives the menthol into the decayed dentin. You cannot remove the decay painlessly in all instances, but you will be surprised to find at times how painlessly you can remove it after applying this remedy.—J. P. BUCKLEY, *American Dental Journal*.

Technique of Amalgam Restorations.—

In restorations with amalgam involving more than one wall, a band matrix should be used. It can be made either of thin copper or the Angle band material, which comes in different widths. I prefer them soldered to fit the case in hand; or I have enough made up of different sizes so that one can be selected without undue delay to fit the teeth under treatment. The band should be firm enough to withstand the lateral pressure of heavy condensation. They should fit as closely as possible at the gingiva, and yet allow for contact points. An orange-wood wedge will nicely preserve the interproximal space, and help to hold the band. If I feel that I can not obtain sufficient anchorage in the tooth to withstand the probable strain, I set one or more pins in the canals. If there be any question about the strength

of a wall, I cut it off far enough gingivally to give good thickness to the amalgam over it. I feel that a single standing wall is more or less a menace to the operation, and unless esthetics require its preservation, I never hesitate to cut backward most heroically. If it is a buccal wall, and that or the adjoining teeth show a tendency to buccal decay, I cut backward under the free margin of the gum, reducing the area of liability as far as possible.

A carborundum stone is one of the best instruments for cutting down the walls when the whole occlusal surface is involved, or in many cases where one or more walls are left standing. A chisel is the instrument with which to test a wall if one is in doubt. If a weak wall be left standing for cosmetic reasons, it should be supported with cement.

The base of the cavity should be broad and flat in proportion to the size of the filling. If one has any doubt about these fillings standing, just study for a minute the base, or anchorage, with the stress it has to bear, and compare it to an incisor pin crown. In the case of the molar there is a broad base, short leverage, and stress largely direct. In the incisor the base is narrow, the leverage long, and the lateral stress in most cases is heavy. Yet no one hesitates to put on an incisor pin crown without a band, or to build up large contour gold fillings.

The walls of the cavity should be nearly parallel, with no overhanging margins to interfere with access in placing the filling, or to fracture in the future. The alloy should be packed with broad-faced serrated instruments, using heavy pressure. A foot plunger in an automatic mallet packs the amalgam well, and is especially good along margins, and for contouring the matrix.

A great deal of care should be used in carving the cusps, reproducing the anatomical features of the particular tooth, and to secure a good articulation. In cases where the cusps of the occluding teeth are worn flat, I think it is advisable to produce more definite cusps than the articulation actually demands. The carving is best done when the filling is partly set. The fissures and fine lines can be worked out with excavators of different patterns, or broken instruments ground to the desired shape. After the filling is finished as much as it can be with the matrix on, the latter should be left on for twenty-four hours. Then remove the band and carefully polish the filling with disks and strips.

In summarizing, I would say that these amalgam restorations are strong, permanent, hygienic, and serviceable operations. They fill a place in practice that cannot be filled by crown or inlay, because of either hygienic or economic reasons.—GEO. R. WARNER, *Items of Interest*.

HINTS, QUERIES, AND COMMENTS.

REPAIRING PORCELAIN FACINGS.

WHERE porcelain facings check or break in bridge or crown work, it is a difficult matter to remove the bridge or crown for repairing it, especially where Richmond crowns are used for anchorage.

By the following method porcelain facings can be replaced very satisfactorily without removing the bridge, or without giving any discomfort to the patient:

Select a facing of proper size and shade to replace the broken one, and drill holes through the gold backing for the pins of the facing; countersink the holes on both sides of the backing, prepare the facing to fit the backing properly, then cut the pins so that

they are just a little longer than the thickness of the backing; split the pins of the new facing with a thin ribbon saw, half the distance of the thickness of the backing.

The facing is now ready to be fastened in place by using a little medium-setting alloy in the pinholes that come next to the porcelain; then press the facing firmly in place, holding it until the operation is completed. With a little hatchet-shaped instrument spread the split pins firmly, as in riveting, and then burnish the alloy in the pinholes. After the alloy has sufficiently hardened, grind the lingual surface down to the original form, and a very slightly and durable piece of work will be the result.

GUSTAVUS NORTH, A.M., D.D.S.

Cedar Rapids, Iowa.

OBITUARY.

SIR MICHAEL FOSTER.

WE regret to record the death of SIR MICHAEL FOSTER of Ninewells, Great Shelford, Eng., one of the most brilliant lights of the scientific world, who died in London, January 29, 1907. Sir Michael had been in failing health for some time past, and while on a visit to London became suddenly worse, dying of heart failure following hemorrhage.

Sir Michael Foster, K.C.B., M.D., F.R.S., D.C.L., D.Sc., LL.D., formerly M.P. for London University, was born March 8, 1836, at Huntingdon, and was therefore seventy-one years of age. He was the son of Mr. Michael Foster, F.R.C.S., a practicing surgeon of Huntingdon, whose family had gained great wealth and social position, and who are well known in the eastern counties.

Sir Michael gained his early education at the Huntingdon Grammar School until the age of thirteen years, when he went to London to

study at University College School in Gower street, where he remained until sixteen years of age, when he matriculated at London University and entered University College. Before taking this step he was recommended to compete for a scholarship at Cambridge, his tutor being confident that even youthful as he was he was sure to succeed. His father, however, being a nonconformist to the Church of England, opposed his son's going to a university where a religious test would prevent his taking a degree. He therefore remained in Gower street, and added one more brilliant name to its distinguished roll of students.

Up to this time he had displayed no special scientific aptitude, but showed marked ability in every study in which he engaged, taking all the principal prizes, and finally in his third year securing all the honors. In the "honors" examination for the B.A. degree he carried off the classical scholarship; and

having received his degree in 1854, when only eighteen years of age, he decided to follow his father's profession, and consequently passed over to the medical side of the college. Here he took the prize for physiology, and thenceforth devoted himself to original work.

At the age of twenty-three he had taken his M.D. degree, and this done he retired to Huntingdon and shared his father's practice.

In 1867 the young Huntingdon surgeon went to London and obtained employment as teacher of practical physiology at University College, where two years later he was appointed professor. In consequence of symptoms of pulmonary disease showing themselves, he spent some months of 1869 on board the cruiser *Union*, employed in the service of the Khedive in the Red Sea.

Later on, in 1870, he was recommended by Professor Huxley and Dr. W. B. Carpenter for the position of prelector of physiology at Trinity College, Cambridge, to which he was elected. The authorities there offered him a Fellowship, but possessing the same religious scruples as actuated his father, and again refusing to conform, he declined the honor.

In 1872 Sir Michael was elected a Fellow of the Royal Society, and in 1881 succeeded Huxley—who had become president—as one of its secretaries, which position he retained until 1903. In 1883, when Cambridge had founded a chair of physiology, Sir Michael was appointed professor, being the first non-conformist professor appointed after the university religious tests were abolished. This post he held for twenty years, and it was here that his greatest work was accomplished. During this period he had the satisfaction of witnessing the establishment of the National Physical Laboratory at Bushey.

In 1899 Sir Michael Foster was president of the British Association, and in the same year he received his knighthood. From 1900 to 1906 he sat as member of Parliament for London University.

Sir Michael was the author of a number of physiological works, the foremost being his "Text-book of Physiology," which has gone through many editions, and been translated into German, Italian, and Russian. He was joint editor of Huxley's "Scientific Memoirs."

Oxford conferred upon him the honorary degree of D.C.L., and Dublin the honorary degree of D.Sc.

The breadth and liberality of his mind was well exemplified upon the occasion of the second annual meeting of the International Dental Federation in Cambridge, Eng., in 1901, when as deputy vice-chancellor of the university of Cambridge he delivered his memorable address of welcome on behalf of the university authorities to the delegates of the dental profession from seventeen different nations. His utterances on that occasion we have frequently referred to in these pages, and whatever exception may be taken to the views which he then expressed, there can be no difference of opinion as to their broad catholicity, their utter freedom from professional prejudice, and their intense portrayal of the loyalty of the speaker to the ideals of scientific truth and justice. Not only that, but the personal attributes of his character demonstrated in many ways the greatness of his mind and heart, and in that noteworthy international gathering he conveyed the impression that though a loyal patriot, a lover of his country, he was endowed with that still greater life-inspiration the love of mankind. His words, his personality, his aggressive internationalism, will ever remain as inspirations to all who were so happy as to have attended the Cambridge meeting of the F. D. I.

On the occasion of the entertainment of the Dutch dentists by the Eastern Counties Branch of the British Dental Association, at Cambridge, Sir Michael made one of his characteristic speeches, in which he coined the phrase "*l'entente internationale*," his conviction being that one of the great aims and probable achievements of science should consist in bringing the nations of the world together.

He was one of the first members of the university to take up the study of Esperanto, of which he was an enthusiastic supporter, and honorary president of the local group.

Sir Michael was twice married, first in 1863 to Georgina Gregory, who died in 1869, and second, to Margaret Sarah Rush, in 1872. He leaves a son and daughter.

SOCIETY NOTES AND ANNOUNCEMENTS.

[JAMESTOWN EXPOSITION, NORFOLK, VA.,
1907.]

JAMESTOWN DENTAL CON- VENTION,

TO BE HELD AT

Norfolk, Va., Sept. 10-12, 1907.

Committee of Organization.

BURTON LEE THORPE, St. Louis, Mo., *Chairman*.

H. WOOD CAMPBELL, Suffolk, Va., *Secretary*.

F. W. STIFF, Richmond, Va., *Treasurer*.

R. H. WALKER, Norfolk, Va.

THOS. P. HINMAN, Atlanta, Ga.

J. E. CHACE, Ocala, Fla.

CLARENCE J. GRIEVES, Baltimore, Md.

The Jamestown Dental Convention, to be held under the auspices of the Jamestown Exposition Company, the Southern Branch of the N. D. A., and the Virginia State Dental Association, will convene at Norfolk, Va., September 10 to 12, 1907. The Jamestown Exposition Company have appointed the above named gentlemen as a Committee on Organization, to elect officers in advance of the meeting, to appoint all committees, to finance the meeting, and to bring it to a successful termination.

The Committee on Organization have appointed Dr. Clarence J. Grievess, Baltimore, Md., general chairman of the Clinic Committee and Supervisor of Clinics.

A number of well-known men will assist him on the General Committee. State clinic chairmen have been selected from every state in the Union. The clinics are to be the principal feature of the convention, and it is expected to bring about the largest and most instructive dental clinics ever held. A surgical clinic will also be held under the supervision of Dr. L. M. Cowardin, Richmond, Va.

The other members of this committee are J. Y. Crawford, Nashville, Tenn., and A. G. Friedrichs, New Orleans, La. Dr. F. W. Stiff, Richmond, Va., is general chairman of the Membership Committee.

Assistant state chairmen have been appointed from every state in the Union. Already membership fees are being sent in, and the promise is for the largest gathering of dentists ever held. Only five essays will be read at the convention, one by Prof. W. D. Miller, another by Prof. G. V. Black, and the other three by well-known southern dentists.

Several exhibits of much interest to the profession will be held under the auspices of the convention; among them the dental manufacture exhibit in charge of Dr. John W. Manning, chairman, Norfolk, Va.; a comparative anatomy exhibit, in charge of Dr. W. M. Bebb, chairman, Los Angeles, Cal., which exhibit will consist of three thousand comparative anatomy specimens, and also numerous other collections of interest; a dental historical exhibit, consisting of ancient instruments, operative and prosthetic work, books and photographs, under the chairmanship of Dr. Wm. H. Trueman, Philadelphia, Pa.; the orthodontia exhibit, showing a large collection of models, etc., under the chairmanship of Dr. H. E. Kelsey, Baltimore, Md. The U. S. Naval dental exhibit, showing 3000 charts of the mouths of midshipmen, will be under the chairmanship of Dr. Richard Grady, the U. S. dental surgeon of Annapolis, Md. The exhibit of the U. S. Army Dental Corps, under the chairmanship of Dr. John S. Marshall, San Francisco, Cal., will also show the equipment, method of keeping records, etc., used by the dental corps.

A full list of the various officers, who are to be elected in advance by the Committee on Organization at their next meeting in February 1907, and of the committees, will appear in due time in the various dental journals. The Committee of Organization is expected to

select officers in advance in order that the officers may be prepared for their duties before the actual meeting of the convention.

A cordial invitation is extended to all reputable members of the profession to become members of this convention, and to assist the Committee on Organization in bringing about one of the best, if not the best, dental meeting ever held.

The Exposition itself offers an excellent opportunity for the busy practitioner to take a delightful vacation, see the wonderful historical and naval and military exhibits at the Exposition, and also to participate in this meeting. The membership fee, which is \$5.00, should be sent to Dr. F. W. Stiff, treasurer, 600 East Grace st., Richmond, Va.

For further information address

H. W. CAMPBELL, *Sec'y*,
Suffolk, Va.

FIRST FRENCH CONGRESS OF STOMATOLOGY.

A CONGRESS of stomatology, styled the First French Congress of Stomatology, will take place in Paris from August 1 to 5, 1907.

The Committee of Organization is as follows: Drs. Galippe and Redier, honorary presidents; Dr. Cruet, president; Drs. Claude Martin of Lyons, and J. Ferrier, vice-presidents; Dr. Chompert, general secretary; Dr. Gires, treasurer.

The Congress will be open to all French and foreign doctors of medicine who are interested in dental and oral science. Subscriptions and communications should be addressed to

DR. CHOMPERT, *General Sec'y*,
182 rue de Rivoli, Paris.

PENNSYLVANIA COLLEGE OF DENTAL SURGERY.

NOTICE TO THE ALUMNI.

ANY alumnus not having received a copy of the souvenir number of the *Pennsylvania Dental Times*, giving the proceedings of the golden anniversary of the Pennsylvania College of Dental Surgery, may secure the same by sending his name and address to

WILBUR F. LITCH, *Dean*,
Eleventh & Clinton sts., Philadelphia, Pa.

AMERICAN DENTAL SOCIETY OF EUROPE.

THE American Dental Society of Europe will hold its next annual meeting in Rome, Italy, on March 29 and 30 and April 1, 1907. A very cordial invitation is extended to members of the profession to be present.

As it is the first meeting of the society in the Eternal City, it is hoped it may be the most enjoyable one in its history.

J. W. GALE, *Hon. Sec'y*,
79 Hohenzollern-Ring, Cologne (Rhine), Ger.

AMERICAN SOCIETY OF ORTHODONTISTS.

At a meeting of the American Society of Orthodontists, held in New York city, December 29, 1906, the following resolutions were adopted:

RESOLVED, That in the opinion of the members of the American Society of Orthodontists the practice of paying a commission, honorarium, or any sort of fee, in consideration of the reference of a patient, is both unwarrantable and unprofessional; and be it

RESOLVED, That the payment of any such commission, honorarium, or fee, by any member of this society, shall be sufficient cause for the expulsion of said member, by vote of the society after conviction; and further be it

RESOLVED, That in case of co-operation in the care of a patient between a general practitioner and an orthodontist, there shall be no division of fees, but each man shall render a separate bill for his personal services.

FREDERICK S. MCKAY, *Sec'y*.

FIRST AUSTRALIAN DENTAL CONGRESS.

THE announcement reached the *Cosmos* too late for insertion previously, of the holding of the First Australian Dental Congress, in Sydney, N. S. W., at the Medical School of the University of Sydney and the United Dental Hospital, February 4 to 9, inclusive, 1907.

Dr. Alfred Burne was chosen president, Ernest Deck treasurer, and W. H. Weston honorary secretary-general.

Contributions of interest were solicited from members of the profession abroad, and it is stated that the proceedings will be published in book form.

ODONTOTECHNIQUE SOCIETY OF NEW JERSEY.

THE Odontotechnique Society of New Jersey will hold its next regular meeting on Saturday, March 2, 1907, at Ahtel-Stetter's, Newark. The paper of the evening will be read by Dr. Corwin of Newark—subject "Adenoids."

Plans are now on foot for a clinic to be held on the afternoon of the date of the April meeting, Wednesday, April 3, 1907, to be followed by a banquet in the evening, at which a paper will be read by Dr. Ellison Hillyer of Brooklyn, on "The Progress—Past and Present—of Prosthetic Dentistry." This will be an important meeting, and one of profit to the profession, and a large attendance is expected.

HENRY J. GIBBINS,
Newark, N. J.

SEVENTH DISTRICT (N. Y.) DENTAL SOCIETY.

THE thirty-ninth annual meeting of the Seventh District Dental Society will be held in Colonial Hall, Rochester, N. Y., March 26 and 27, 1907.

We expect to have the largest and best meeting in the history of the society, having secured assistance from some of the most prominent men in the profession. From the present outlook we are going to have a very large exhibit. Arrangements are being made for reduced rates on the railroad.

C. W. LA SALLE, *Sec'y*,
Rochester, N. Y.

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

THE National Association of Dental Examiners will hold their twenty-fifth annual meeting in Minneapolis, Minn., beginning Friday, July 26th, and continuing through the 27th and 29th. A large attendance of delegates is earnestly requested.

Accommodations have been secured in the leading hotel of Minneapolis—The West Hotel. Rates will be as follows: Rooms without bath, \$1.00 per day for each occupant; with bath, \$2.00 per day for one person, and \$1.50 per day for each additional person in room. The hotel is run on the

European plan. Any room in the hotel is capable of accommodating two people. All the rooms have telephone connection, and hot and cold water. Railroad rates will be given later.

The Committee on Colleges, Joint Conference Committee, Tabulation of Examining Boards' Reports, and the Committee for Promoting a System of Credits and Uniformity of Examinations will all give exceedingly interesting reports, valuable to all the members of the association.

CHAS. A. MEEKER, *Sec'y-Treasurer*,
29 Fulton st., Newark, N. J.

MONTANA STATE DENTAL SOCIETY.

A MEETING of the Montana State Dental Society will be held in Helena, April 12 and 13, 1907.

W. E. TREBSE, *Sec'y*,
Helena, Mont.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE forty-third annual convention of the Connecticut State Dental Association will be held at New London, Conn., April 16 and 17, 1907.

An excellent program is assured.

EDWARD S. ROSENBLUTH, *Sec'y*,
1051 Main st., Bridgeport, Conn.

GEORGIA STATE DENTAL SOCIETY.

THE next annual meeting of the Georgia State Dental Society will be held in Atlanta, May 7, 8, 9, and 10, 1907. All ethical practitioners are cordially invited to attend.

D. H. MCNEILL, *Cor. Sec'y*,
Athens, Ga.

OREGON STATE DENTAL ASSOCIATION.

At the last meeting of the Executive Committee of the Oregon State Dental Association, it was decided to hold the annual meeting in Portland, Ore., May 9, 10, and 11, 1907.

JEAN CLINE, *Sec'y-Treasurer*,
Portland, Ore.

NEW YORK STATE DENTAL SOCIETY.

THE thirty-ninth annual meeting of the Dental Society of the State of New York will be held in Albany, May 10 and 11, 1907.

Essays will be presented by the following members of the profession: W. D. Miller, Berlin; A. H. Peck, Chicago; Charles McManus, Hartford; Clarence J. Grieves, Baltimore; G. V. I. Brown, Milwaukee; L. C. F. Hugo, Washington; Nelson T. Shields, New York; I. C. Curtis, Fulton; S. L. Goldsmith, New York (Report of Correspondent); E. Howard Babcock, Brooklyn (Report of Committee on Practice); Emanuel Muntz, Buffalo (Report of Committee on Scientific Research).

A full list of clinics is being arranged, and a complete program will be announced later.

CHAS. S. BUTLER, *Sec'y*,
Buffalo, N. Y.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

THE tenth annual session of the Southern California Dental Association will be held in Los Angeles, May 6, 7, and 8, 1907, at the same time that the Imperial Council of Mystic Shrine meets here, and all members of the dental profession contemplating visiting southern California at that time will confer a favor upon the association by notifying

CHAS. M. BENBROOK, *Sec'y*,
455 S. Broadway, Los Angeles, Cal.

VERMONT STATE DENTAL SOCIETY.

THE thirty-first annual meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 15, 16, and 17, 1907.

The society has in the past held most successful meetings, and we have every reason to expect that this will surpass any previous one, as a very interesting program has been prepared by the committee, and will be mailed in due time. Vermont has the largest per cent. of membership in its state society of any state in New England, and we hope to see every dentist in the state who is eligible a member.

THOMAS MOUND, *Sec'y*,
Rutland, Vt.

ARKANSAS STATE DENTAL ASSOCIATION.

THE Arkansas State Dental Association will hold its annual meeting at Eureka Springs, Ark., May 29, 30, and 31, 1907.

HENRY P. HOPKINS, *Sec'y-Treas.*,
Argenta, Ark.

KENTUCKY STATE DENTAL ASSOCIATION.

THE next annual meeting of the Kentucky State Dental Association will convene at Louisville, Ky., May 20, 21, and 22, 1907. We anticipate a most interesting and profitable meeting. A cordial invitation is extended to the profession.

W. M. RANDALL, *Sec'y*,
Louisville, Ky.

LAKE ERIE DENTAL ASSOCIATION.

THE forty-fourth annual meeting of the Lake Erie Dental Association will be held at Hotel Rider, Cambridge Springs, Pa., on May 21, 22, and 23, 1907.

Upon our program this year are men of exceptional merit, and we are pleased to invite all reputable dentists and their friends to this beautiful place for convention purposes.

V. H. MCALPIN, *Sec'y*,
Warren, Pa.

WASHINGTON UNIVERSITY DENTAL DEPARTMENT.

MEETING OF ALUMNI.

A MEETING of the Alumni Association of Washington University Dental Department (Missouri Dental College) will be held May 20, and 21, 1907, at the college building, 2645 Locust st., St. Louis, Mo.

A number of prominent essayists and clinicians have been secured, and an interesting and instructive program will be presented. Adequate space has been secured for the various manufacturers' exhibits; this will be a noteworthy feature of the meeting. All ethical practitioners are invited.

A. J. PROSSER, *Chairman*,
F. W. HORSTMANN,
CHAS. HERBERT.

SOUTH DAKOTA DENTAL SOCIETY.

THE twenty-fifth annual meeting of the South Dakota Dental Society will be held at Sioux Falls, June 5, 6, and 7, 1907.

A most interesting program has been arranged, and we want to see the largest attendance the society has ever had. A larger membership is desired, and every eligible dentist in the state should become a member. A special invitation is extended to South-eastern Minnesota and Northwestern Iowa dentists to attend.

FERDINAND BROWN, *Sec'y*,
Sioux Falls.

INDIANA STATE DENTAL ASSOCIATION.

THE forty-ninth annual meeting of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, June 11, 12, and 13, 1907. The Executive Committee has arranged an unusually interesting program for this meeting. A cordial invitation is extended to the profession to be present.

CARL D. LUCAS, *Sec'y*,
Indianapolis, Ind.

TENNESSEE STATE DENTAL ASSOCIATION.

THE annual meeting of the Tennessee State Dental Association will be held at Knoxville, Tenn., July 9 and 10, 1907. A splendid program is being arranged by the Executive Committee, and a most cordial welcome is extended to all.

R. J. MCGAVOCK, *Sec'y*,
Columbia, Tenn.

NEW JERSEY STATE DENTAL SOCIETY.

THE thirty-seventh annual meeting of the New Jersey State Dental Society will be held in the Auditorium at Asbury Park, N. J., commencing 10 A.M. July 17th and continuing through the 18th and 19th. The headquarters will be at the Hotel Columbia, at the rates of \$3.50 and \$4.00 per day, and all reservations must be made before July 1st.

Prominent dentists have signified their in-

tention of reading papers, and the clinics will all be of a new and novel nature. Clinic committee in charge of Charles H. Dilts, Trenton, N. J.; exhibit committee in charge of Walter Woolsey, Elizabeth, N. J. Programs will be out June 15th.

Last year over eight hundred dentists registered in attendance. The Auditorium where the meeting is held is the largest and best adapted building on the Jersey coast. Cut off the week of July 15th, and be with us.

CHARLES A. MEEKER, *Sec'y*,
29 Fulton st., Newark, N. J.

MASSACHUSETTS BOARD OF REGISTRATION.

A MEETING of the Massachusetts Board of Registration in Dentistry will be held in Boston, March 6, 7, and 8, 1907, for the examination of candidates. Application blanks and further information may be obtained from

G. E. MITCHELL, *Sec'y*,
Haverhill, Mass.

RHODE ISLAND BOARD OF REGISTRATION.

A MEETING of the Rhode Island Board of Registration in Dentistry, for the examination of candidates, will be held at the Statehouse, Providence, R. I., Tuesday, Wednesday, and Thursday, March 19, 20, and 21, 1907. Application blanks may be obtained of

W. S. KENYON, *Sec'y*,
301 Westminster st., Providence, R. I.

MINNESOTA BOARD OF DENTAL EXAMINERS.

THE Minnesota State Board of Dental Examiners will hold its next regular meeting at Minneapolis, in the Medical Building of the State University, on April 2, 3, and 4, 1907. All applications must be in the secretary's hands by 11 o'clock of April 2nd. Candidates will be furnished all necessary blanks and such other information as is necessary, upon application to

GEO. S. TODD, *Sec'y*,
Lake City, Minn.

ARIZONA BOARD OF EXAMINERS.

THE Board of Dental Examiners of Arizona will meet at Phoenix, April 8, 9, and 10, 1907, for the purpose of holding examinations. The fee, twenty-five dollars (\$25.00), should be in the hands of the secretary twenty days before date of meeting. For further information, address

W. P. SIMS, *Sec'y*,
Box 58, Bisbee, Ariz.

ARKANSAS BOARD OF DENTAL EXAMINERS.

THE Arkansas State Board of Dental Examiners will hold examinations at Eureka Springs, Ark., May 27 and 28, 1907.

A. T. McMILLIN, *Sec'y*,
Little Rock, Ark.

NEBRASKA BOARD OF EXAMINERS.

THE next meeting of the Nebraska Board of Dental Examiners will be held at the State-house, in Lincoln, Nebr., May 29, 30,

and 31, 1907. All applicants for examination must have their applications in the hands of the secretary five days before this date. For further information address.

C. F. LADD, *Sec'y*.
1241 O. st., Lincoln, Nebr.

TEXAS BOARD OF DENTAL EXAMINERS.

THE Texas State Board of Dental Examiners will hold their next regular meeting at San Antonio, Texas, June 10, 1907, at 10 A.M. For further information address

C. C. WEAVER, *Sec'y*.
Hillsboro, Texas.

CALIFORNIA BOARD OF DENTAL EXAMINERS.

THE next examination of the Board of Dental Examiners of California will be held in Los Angeles beginning June 10, and in San Francisco beginning June 17, 1907.

C. A. HERRICK, *Sec'y*,
Jackson, Cal.

ORIGINAL COMMUNICATIONS.

ORTHODONTIA AS A PROPHYLACTIC MEASURE.

By **FREDERICK C. KEMPLE, D.D.S., New York, N. Y.**

(Read before the New York Odontological Society at its regular monthly meeting,
November 20, 1906.)

I WISH to thank your committee for the honor conferred upon me by their invitation to present a paper to this society. In accepting their invitation I hoped that I might be able to present a few facts setting forth the importance of occlusion and use of the teeth as a factor in the development of the entire internal face, as well as in maintaining a normal healthy condition of the tissues of the mouth and the upper respiratory tract.

Normal dental arches can no longer be considered from the esthetic standpoint alone, nor can orthodontia be regarded as purely cosmetic. The day is fast approaching when a close relationship between orthodontia and general prophylaxis must be recognized.

Anything that *guards* or defends against disease is a "prophylactic." Any

measure that tends to increase physiological resistance to the invasion of and propagation of pathogenic germs, and thus lessens the liability of the individual to disease, is a "prophylactic measure." If it can be demonstrated that orthodontia as practiced today tends to the physical improvement of the patient by increasing his power of resistance to disease, then orthodontia must have a place as a prophylactic measure.

Throughout this paper I shall make free use of the opinions of men in both the medical and dental professions who have given much study to pathological conditions of the oral and nasal cavities.

From almost every part of the field of medicine we hear of the baneful effects of *mouth-breathing*.

Dr. Coakley, in his "Diseases of the

Nose and Throat," says, "Of the functions of the nose, that which is vitally the most important to the individual is the respiratory."

Dr. Holt, in his "Diseases of Infancy and Childhood," says, "In consequence of difficult breathing children sleep in all sorts of positions, lying upon the face, sometimes upon the hands and knees, and often toss restlessly about in the vain endeavor to find some position in which respiration is easy."

It has been commonly observed in those cases where "nasal breathing has been obstructed from infancy, that there are often found those deep lateral depressions of the lower part of the chest with prominence of the sternum known as 'pigeon-breast,' due to interference with pulmonary expansion." (Holt.) In a large proportion of these cases long-continued mouth-breathing results in impaired hearing due to implication of the Eustachian tube; persistent coughs; hoarseness; bronchial asthma; headaches; impaired general health from lack of oxygen and loss of sleep. The growth may be stunted, the facial expression dull and stupid. These children are languid, listless, and often depressed, and in school are frequently regarded as mentally deficient. These symptoms are not all present in each individual case, but vary in number and severity with each patient.

Mouth-breathers are always in more danger from infectious diseases than normal nasal breathers, because of the lessened physiological resistance of the post-nasal, pharyngeal, and laryngeal tissues, coupled with the fact that the atmosphere is carried directly to these weakened parts without having been filtered and moistened as in nasal breathing.

Some bacteriologists claim that the secretions of the nasal mucous membrane possess bactericidal properties, retarding the growth of some bacteria and preventing the development of others. It is a well-known fact that there are very few bacteria found well within the nasal cavities, which condition would make the claim appear highly probable.

Where the nasal respiratory function has been interfered with for an extended

time, the bony framework of the nose becomes contracted through atmospheric pressure and disuse. If this condition be allowed to continue till the bones of the face have firmly united, "the capacity for nasal breathing is permanently fixed," so far as surgical aid from the rhinologist is concerned.

Dr. Kyle, in his "Diseases of the Nose and Throat," referring to adenoids says, "Even should the gland structure causing the obstruction be removed, while its ablation may relieve the naso-pharyngeal symptoms, it cannot possibly increase nasal respiration, other than by lessening the engorgement of the submucosa. This fixity of the bones of the face may leave the individual a confirmed mouth-breather."

Whether it be due to inflammatory organization in consequence of interference with function, or to other cause, it is a fact that adenoids are very liable to recur in young children, no matter how thoroughly the operation for their removal may have been performed. I have in mind at the present time two children, both of whom I met within the month, a little girl aged eleven years and her brother aged nine. These children were operated upon almost two years ago for the removal of post-nasal obstruction, when they were aged respectively nine and seven years, yet they continue to breathe through the mouth.

Dr. Kyle states that in these developmental deformities due to nasal obstruction, little can be done by the rhinologist toward increasing the nasal space for breathing after the age of seven years.

If these cases—where the bones have become so fixed that even after the removal of the causative obstruction nature cannot restore normal conditions—were placed in the hands of the orthodontist, and he worked in conjunction with the rhinologist, instead of leaving the individual a confirmed mouth-breather the post-nasal space would in many cases be increased, and normal nasal breathing restored without a conscious effort on the part of the patient. (Fig. 1, A, B.) Of course this refers to patients under fourteen or

fifteen years of age, the development of the internal nose being almost complete at that time.

In thus playing an important part in the restoration of normal nasal function and normal lip function—thereby lessening the liability of the individual to all those infectious diseases to which the

as I am able to see, is the keynote of all that Dr. Smith has taught on the subject.

The part which the patient takes in this prophylactic treatment becomes an important factor in making a prognosis. Any condition of the mouth which tends to make the thorough cleansing of the teeth by the patient himself a difficult

FIG. 1.

Age thirteen years. A: Diameter of vault in molar region, 1.60 in.; at second bicuspid, 1.33 in.; at first bicuspid, 1.38 in.; at canine, 1.25 in. B: Diameter in molar region, 2.05 in. (expansion 0.45 in.); at second bicuspid, 1.87 in. (expansion 0.54 in.); at first bicuspid, 1.68 in. (expansion 0.30 in.); at canine, 1.54 in. (expansion 0.29 in.).

mouth-breather is peculiarly exposed—orthodontia certainly establishes a claim as a prophylactic.

As dentists, however, we have principally to consider malocclusion and its relation to "oral prophylaxis"—a term which I understand to imply perfect cleanliness of the oral cavity, a condition that can be maintained only through the constant and united efforts of both patient and operator.

Dr. Miller, who perhaps has given more scientific study to the etiology of dental caries than has any other member of the profession, in speaking of its prevention says, "Under all conditions the chief thing is the thorough mechanical cleansing of the teeth." And this, so far

operation, lessens, inversely with the difficulty, the probability of a favorable result. When the dental arch is constricted and the teeth are crowded and overlapping (Fig. 2, A), forming triangular spaces into which food debris is forced by stress of mastication, it is impossible for the patient to keep those teeth clean. Bacteria which possess high fermentative and acid-forming activity lodge in those spaces undisturbed, and the rapidity with which they carry on their destructive work, either in producing caries or pyorrhea, depends entirely upon the degree of resistance offered by the surrounding tissues.

Since first the study of the etiology of dental caries was taken up by the dental

profession, "irregularities of the teeth" has been given and universally accepted as one of the potent predisposing causes of dental decay.

If perfect cleanliness of the teeth will prevent dental caries—and of this there seems to be small doubt—then that condition of regular alignment of the dental arches, normal occlusion, and normal articulation (Fig. 2, B) which best facili-

tifical. In some the crowns of the teeth are so well formed and arranged and knuckle up together so perfectly that as long as the interdental papillæ are in a healthy condition there is little possibility for food to lodge. In others we find the food sticking between the teeth everywhere. There can be no doubt that this circumstance is of very considerable consequence in regard to the origin and

FIG. 2.

Age fourteen years.

tates perfect cleanliness is a condition which must necessarily contribute much to prophylactic treatment of the oral cavity. In the normal dental arch, "Nature has given us an apparatus that is in a large measure self-cleansing," while in those mouths where malocclusion exists, every protected surface of a tooth invites an accumulation the presence of which favors dental decay and gingival irritation.

In a paper entitled "A Study of Certain Questions Relating to the Pathology of the Teeth" (Cosmos 1904, vol. xlv, p. 991), Dr. Miller refers to the facility with which different dentures are cleansed, in the following words: "Different dentures show very marked differences in regard to the efficiency of cleansing processes, whether spontaneous or ar-

progress of caries." "All the cases of immunity to caries which I have examined during the last few months have related to dentures where there was little tendency to retention of food particles." "The comparative immunity of the lower front teeth to caries is due in a great measure to the fact that the food particles do not readily lodge about them." If for any reason food particles are retained, "then these teeth decay as readily as any others."

In almost every case of malocclusion where the lower front teeth are crowded and overlapping, you will find some of them attacked by caries—some so far decayed, because of their broad surfaces of contact, as to be almost beyond the hope of permanent retention. (Fig. 3, A, B.) This is true even in those mouths where

the other teeth are comparatively free from decay.

Concerning the etiology of pyorrhea, there have been theories countless almost as the sparkling orbs of heaven. It has been the subject for heated debate since first the attention of the profession was directed to it by Dr. Riggs, and it may continue to furnish food for controversy till science shall have eliminated

there must still be some predisposition on the part of the membrane which makes it specially liable to such deposition. This predisposition is to be found in impaired nutrition and lowered vitality in consequence of mechanical strain from overcrowding of the dental arch."

Professor Armand Deprès attributes "considerable importance to the overcrowded condition of the dental arch as a

FIG. 3.

Age thirteen years. Lower lateral incisors badly decayed.

it from the catalog of human afflictions. There are those in the profession who maintain that this disease is entirely constitutional; others who claim it to be of purely local origin, and yet others who believe it results from both constitutional and local causes. Investigations have been carried on along these various lines, positive conclusions have been deducted, and these conclusions just as positively controverted. Fortunately we have not to weigh these numerous evidences, but have only to see, if possible, what relation malocclusion may bear to pyorrhea.

Dr. Pierce, in referring to the exciting causes of the disease says, "But even admitting the deposition in the pericemental membrane of waste products of nitrogenous metabolism in combination with calcium salts derived from the blood,

predisposing cause in the development of pyorrhea." Dr. Bödecker believes pyorrhea to be of both constitutional and local origin, and in specifying a list of local causes mentions first of all the "faulty articulation of the teeth." Drs. Black, Marshall, Burchard, Kirk, and many others, recognize malocclusion as one of the contributory causes of pyorrhea. (Fig. 4, A, B.)

A short time ago I had the pleasure of seeing a number of slides shown by Dr. Schamberg. These slides were skiagraphs showing molars which had come into malocclusion or tipped out of the normal through the loss of an adjoining tooth. On the under or protected surface of every one of these teeth was a pyorrhea pocket or area of necrosis.

Chance has long since ceased to have

a place among men of science. Any present condition is but the result of the natural sequence of cause and effect. The co-existence of a crowded dental arch and dental caries, or the co-existence of mal-occlusion and pyorrhea, is not merely a coincidence, but in many cases a consequence—the one owing its existence to the other.

Dr. Campbell reports a case among the poor of London, of a man in his fiftieth year whose teeth were all perfectly sound, a very unusual condition among this class of people. In seeking an explanation Dr. Campbell elicited the fact that "this man was unable to swallow his food without chewing it very thoroughly, and upon giving him a piece of bread with the re-

FIG. 4.

A
Age twelve years. Lower laterals, canines, and first bicuspid predisposed to pyorrhea. B: Predisposition to pyorrhea overcome by correction of the occlusion.

It is very probable that the various organs of the body were prepared for their special physiological functions through a process of variation and natural selection due to environment, and to the necessity for using or not using certain parts of their anatomy. Naturalists are observing anatomical changes going on today. The ostrich, through his desire to walk, has lost his power to fly.

The effects of the disuse of the teeth for masticatory purposes are readily seen in those mouths where, from sensitiveness of a tooth or any cause, the patient uses only one side of the mouth. The accumulation of food debris in the disused portion, the calcic depositions about the necks of these teeth, and the concomitant inflammation of the gum tissue in this region, all tell the story of what mastication does for the teeth and mouth.

quest that he chew it in the ordinary way, found that he subjected it to one hundred and twenty bites before swallowing it. The temporals and masseters were enormous, and the nasal passages well developed, while the oral mucous membrane was unusually healthy."

The dental hygiene being taught today is only an attempt to restore by artificial means the health of those tissues of the oral cavity that are suffering from disuse. It is false doctrine to teach, as one gentleman endeavored to in his discussion of a paper at the meeting in Washington of the Southern Branch of the National Dental Association, that "Our teeth are not for mastication in our present civilization;" that "mastication and insalivation are not necessary processes at all."

Professor Irving Fisher of Yale University recently conducted some experi-

ments to discover whether attention to slow eating and enjoyment of the food would affect the working powers of the individual. The experiments were made with nine Yale students, and lasted four and one-half months. The rules of the experiment were, first, thorough mastication of the food, with the attention directed to its taste and enjoyment; and second, implicit obedience to the appetite. The men ate nothing which they did not choose of their own free will. Nothing was set before them except as ordered by them, and meats were available three times a day. They led sedentary lives, and took no more exercise than they had been accustomed to before the experiment began.

At the end of the first half of the time the men had improved fifty per cent. in endurance. At the end of the second half they were able to do double the amount of physical work—as shown by gymnasium tests—that they were capable of doing at the beginning of the experiment. It was also found at the close that

their consumption of flesh foods had decreased to one-sixth of the original amount.

The trituration and insalivation of the food are not the only important functions of mastication. In normal occlusion of the teeth the evenly distributed force of impact during the process of mastication affords a stimulus not only to the teeth, but to the membranes of the mouth, the peridental and alveolar tissues, and even to the maxillæ and mandible, which is beyond our power to measure.

Orthodontia is not a panacea, but normal occlusion of the teeth is a very important factor in producing the normal development of the internal face, as well as maintaining a normal hygienic condition of the mouth by the natural processes of mastication.

When an organ is no longer called upon to perform the function for which nature intended it, just so soon does it begin to lose its power of function and to atrophy, and is very likely to become the seat of disease.

ORTHODONTIA: OPENING THE BITE IN THE REGULATION OF THE TEETH: A METAL FLANGE FOR IMPROVING THE ANCHORAGE OF APPLIANCES, MOVING TEETH, AND FOR HARMONIZING THE OCCLUSION.

By V. H. JACKSON, M.D., D.D.S., New York City.

(Read before Section I of the National Dental Association, Atlanta, Ga., September 18, 1906.)

IN the practice of orthodontia, cases are presented with irregularities of the teeth in which the abnormal occlusion requires the opening of the bite for their correction; that is, some of the teeth that should have a labial occlusion have a lingual occlusion, or the reverse, being interlocked by the teeth of the opposite arch. In some instances the movement of these teeth, in their correction, is greatly facilitated by opening the bite so that they

will not be interfered with by the teeth of the opposite arch during their movement.

Of the large number of cases of irregularity of the teeth treated, but a small percentage require the appliance to be arranged to open the bite for their correction.

When the jaws are at rest the teeth are not in occlusion, the full occlusion of the teeth taking place only at the time of

mastication, during the act of swallowing, during extreme muscular or physical strain, while enduring pain, and at times during sleep, when suffering caused by some nervous disorder prompts the gritting of the teeth.

The opening of the bite is the operation which consists in the placing of an

upper or lower arch; gold caps, and sometimes plates of gold or silver, were fastened to the occluding surfaces of the molars or bicuspid. Later, vulcanite in the form of a plate, with the sides raised as required, was used for this purpose, the thickened part being made to extend over the grinding surface of the teeth to

FIG. 1.

FIG. 2.

object between the upper and lower teeth at the most favorable location, so that the teeth of the arches cannot occlude. The advantage of this practice has been recognized for a great many years, and numerous efforts have been made to construct an apparatus for opening the bite that could be easily applied and retained, and at the same time be of service to the patient during the function of mastication.

With the early methods of opening the bite, blocks of ivory, gold, or silver were employed by being placed between the occlusal surfaces of the teeth, and usually by tying them to those of either the

occlude with those of the opposite arch, as illustrated by the Coffin method.

The opening of the bite is more commonly employed for moving upper incisors from a lingual to a labial occlusion, or lower incisors from a labial to a lingual occlusion.

Fig. 1 illustrates a case in which the upper incisors closed back of the lower ones to such an extent as to require the opening of the bite to facilitate their outward movement.

An appliance for moving the incisors outward, and at the same time open the bite, was made as illustrated in Fig. 2. The appliance was removable, made on a

plaster cast in the usual manner with partial clasps, spring clasps, base-wire, and a semicircular spring with U-shaped loops. The spring clasps are passed over the first bicuspid and first molars for anchorage.

The opening of the bite can be begun at any stage of the regulation of the teeth at which it is found necessary. For this purpose the appliance is adjusted on the

FIG. 3.

cast, and a strip of plate metal, No. 36 gage or thinner, is placed across the teeth from before backward. (Fig. 3.) The metal is fitted into the depressions of the teeth as well as may be by successively pressing it gently with a piece of wood, ivory, or a metal instrument, and it need not necessarily be swaged. The ends of the plate metal are then narrowed with the scissors sufficiently to permit one end to be passed underneath and doubled around the mesial wire of the spring clasp on the bicuspid, and the other around the distal wire of the spring clasp on the molar. Wax is then built up on this part, and the appliance is inserted in the mouth for the purpose of securing the bite, and at the same time to determine how much the upper and lower arches should be separated to permit the upper incisors to be moved outward without interference. The appliance is then replaced on the cast, the edges of the wax trimmed smooth, and moldine pressed over it to form a mold. The moldine is taken off to remove the wax, and replaced, with a hole left in the side. Chemically pure tin or jewelers' soft solder is melted in an iron spoon and poured into the mold. This forms a block of metal on the appliance in the space pre-

viously occupied by the wax, causing a good articulation with the lower teeth.

Another method, that is usually preferred, is to build up the raised part by flowing on the plate metal jewelers' soft solder or pure tin, using the soldering iron, after placing a piece of properly shaped moldine around this part of the appliance to form an outline. The surface of the solder is then dressed with a coarse file, and the parts properly finished and polished; or a bar of metal can be soldered to the plate metal and dressed to form a good occlusion.

The upper incisors are moved outward with the looped spring in the usual manner, as shown in Fig. 2, and when they have passed sufficiently in front of the lower incisors the metal is dressed away from the grinding surface from time to time as much as the position of the incisors will warrant until it is all removed, which leaves the appliance free, as ordinarily made, permitting the teeth to rest together in occlusion. The same appliance is used for retaining the teeth when desired.

FIG. 4.

The opening of the bite in this manner, when not excessive, does not interfere with mastication or with speech, the appliance is inconspicuous, is suitable for any age, and for the correction of any form of irregularity requiring the opening of the bite. A few important cases will now be described and exhibited.

Fig. 4 illustrates a case of unilateral occlusion in a boy aged ten years. The upper arch was of good form, excepting that the incisors were very prominent,

with slight spaces between them, and resting over the lower lip. The lower arch was narrow, the incisors extruding and apart from one another.

The occlusion of the deciduous and permanent molars on the left side was good, while on the right side, the lower arch being narrow, there was an entire lack of occlusion, the lower teeth closing inside of the line of the upper ones. From lack of use, the molars on that side had become somewhat elevated in their sockets, causing the upper teeth to lap outside the lower ones to such an extent as to cause a wearing down on the sides where they rested together. This lapping of the teeth prevented the regaining of a natural occlusion without mechanical interference.

With these conditions present, it would be useless to apply simple force for the expansion of the lower arch without opening the bite, as any force applied

on the right side to clear. In addition to the built-up portion on the left side a metal flange was attached to it for increasing the anchorage. The flange was made of plate metal No. 22 gage, and soldered to the lingual side of the anchorage portion of the appliance extending from front to back, projecting upward about three-sixteenths of an inch, and fitting the palatal faces of the upper molars. Opening the bite in this manner prevented the locking of the teeth on the right side, and the flange resting on the lingual faces of the upper molars in oc-

FIG. 6.

FIG. 5.

clusion prevented the position of any of the teeth changing on that side as pressure was applied by the spring base-wire in forcing outward the teeth on the right side. (Fig. 6.)

The expanded condition of the arch and the same appliance after twelve visits

FIG. 7.

for moving outward the lower right molars would also move the upper molars outward more or less through the occlusion, and the same force, if continued, would move the teeth of the left side of the arch outward, spoiling the good occlusion which existed on that side. To overcome these conditions, an apparatus was constructed as shown in Fig. 5. The usual appliance with a lingual base-wire for expanding the lower arch was first made. The bite was opened by building up with metal the anchorage portion of the apparatus on the left side sufficiently to permit the elevated molars

is shown in Fig. 7, the patient calling at intervals of not less than one week.

The arch being expanded sufficiently,

the flange and the metal block for opening the bite were removed, permitting the teeth on the right side of the arch to rest in occlusion with the teeth of the upper arch, and the same appliance for retaining was continued in use.

The upper incisors were much too prominent and needed to be moved inward, but as the lower incisors naturally antagonized with the gum back of them,

FIG. 8.

their position could not be corrected until the lower incisors were depressed in their sockets. This was accomplished by an appliance adjusted in the upper arch, as illustrated in Fig. 8. It was made with a palatal base-wire, and anchored to the teeth by partial clasps and spring clasps in the usual manner. A semicircular spring with U-shaped loops was arranged to cross the labial faces of the incisors, with the ends, one on each side, passing over the arch at the junction of the canines with the first deciduous molars, to be united with solder to the anchorage portions of the appliance.

To the anterior part of the appliance, back of the incisors and canines, was attached a semicircular piece of plate metal about No. 22 gage, forming a table, resting high above the gum. This opened the bite by directing all of the force of occlusion on the lower incisors, gradually depressing them in their sockets. The table was sustained and prevented from pressing against the gum during occlusion by two small wires—each curved into a small loop, the end of the loop being bent upward and hooked

over the canine—one on each side of the arch, with the ends soldered to the table and anchorage.

As the lower incisors were depressed in their sockets, the anterior part of the metal table was dressed away a little from time to time, and the loops of the semicircular spring were closed slightly for forcing inward the upper incisors.

Care should be exercised in not causing too much force on the semicircular spring at one time. The anterior edge of the table should be dressed away a little in advance of the movement of the teeth. The only exceptions to this are when the teeth are to be rotated, or when they require to be depressed in their sockets.

The table is sometimes arranged to tip forward in order to form an inclined plane for forcing the lower incisors outward at the same time they are being depressed, or tipped backward for forcing the lower incisors inward as they are being depressed.

An apparatus with a flange, as described in connection with Fig. 5, is utilized in my system for many purposes. In expansion of the arch when the teeth are to be moved to a considerable extent,

FIG. 9.

it is sometimes difficult to harmonize the teeth of the upper arch with those of the lower to establish a good and permanent occlusion. Fig. 9 illustrates an expanding and equalizing device adjusted in

the upper arch, with flanges attached on each side projecting downward from the lingual surface. The appliance is made with partial clasps and spring-clasp attachments, connected by a large palatal base-wire. Spurs are extended from the device to the grinding surface of the upper teeth, in order to prevent the apparatus from being pressed against the gum.

The flanges, *a, a*, are made of heavy plate metal, and shaped to project suffi-

flat metal springs. This device is applicable for similar purposes in the lower arch in conjunction with the lingual base-wire. It seldom interferes with mastication. The appliance can be removed by the patient for cleansing it as would any other ordinary appliance.

Fig. 10 illustrates the position of the teeth of a patient forty-one years of age. It was a case of unilateral prognathism, in which the opening of the bite was necessary for its correction.

FIG. 10.

ciently on the lingual surface of the lower molars, bicuspsids, and canines in occlusion, to guide and cause them to articulate with the upper ones. In locating the flanges on the appliance it is well to take a bite as for making artificial teeth. Their general contour can be crimped to fit the lower teeth, or left smooth. When it is not desired to change the shape of the flanges they can be thickened with solder. Bending outward the base-wire slightly from time to time broadens both the upper and lower arches. The flanges can be bent outward or inward, as required, to further adjust the occlusion. When desirable, the flange can also be extended around the anterior part of the arch, as for correcting a receding mandible. For some conditions the flanges may best be made to project in the form of independent

The left upper canine and the central and lateral incisors closed far inside of the lower teeth, the lower canine and incisors projecting nearly to the upper gum in front of them, and some of the teeth were considerably worn down. Several molars and bicuspsids of the upper and lower arches were absent, making it somewhat difficult to secure a good anchorage for the correction of the irregular teeth. A device was arranged to open the bite, in order to thus facilitate the movement of the irregularly placed teeth, and at the same time to secure additional anchorage by making possible the attachment of the appliance to the upper incisors and canine on the opposite side of the arch. A spring-clasp attachment was arranged over the upper left first molar, the only remaining anchorage tooth on that side, and a spring-clasp attachment over the

upper right second bicuspid—the first bicuspid having been removed—with partial clasps on the first molar, canine, lateral and central incisors. (Fig. 11.) Small short wires were shaped to pass over the incisal edge at the junction of

by building additional solder on the partial clasps on the incisors and canine, which had been left unusually broad, and on to strips of plate metal, one extending from the canine across the space and over the bicuspid, and the other over the molar

FIG. 11

FIG. 12.

the central incisors, lateral, and canine, resting on the partial clasps, with the ends on the labial side extending perpendicularly toward the gum to assist the anchorage and to prevent the appliance from being dislodged during mastication.

The sides of the device were connected by a palatal base-wire. A semicircular spring with two U-shaped loops was arranged with the ends extending to the anchorage portions. All of the parts were united with solder. The bite was opened

on the opposite side of the arch. The bite being opened in this manner did not interfere with mastication, and permitted the outward movement of the instanding teeth when force was applied by means of the looped spring. The anterior part of the spring was retained by a lug on a collar cemented to the canine. The regulating was completed in a limited time and with no special discomfort to the patient. In Fig. 12 is seen the position of the teeth, and the partial upper and lower

plates, which served for retaining the teeth and which filled the vacancies in place.

Fig. 13 illustrates the case of a patient thirteen years of age. The teeth were

FIG. 13.

very large, and the cheek bones prominent. The upper arch was broad, and the incisors tipped inward. The lower arch was narrow, the molars on the left side and the second molar on the right side closing entirely inside of the line of the upper ones. The incisors were extruded, antagonizing against the gum back of the upper incisors. As the patient lived in central New York, and required eight hours' time to reach my office, he could therefore make visits only at long intervals.

The lower arch was first expanded laterally with an expanding device as shown in Fig. 14. The appliance was anchored

FIG. 14.

by partial clasps and spring-clasp attachments to the bicuspid and first molars. The anchorage portions were connected

by a lingual base-wire, which passed below the gum line, and extending backward, entered the anchorage from below upward. The base-wire, entering the center of the anchorage portion in this manner, permits of its being utilized for the expansion of the whole arch laterally, or for the lateral expansion of the distal or anterior portion of the arch as required. The base-wire extending far back on each side to enter the anchorage, also has the advantage of the lengthened arms, as it is thereby rendered more springy and generally more effective in expanding laterally the anterior part of the arch.

The second molar was badly tipped within the arch, and just erupting. In such a case it is generally found an advantage to move the teeth outward by a spring rather than by the general anchorage with partial clasps. The spring

FIG. 15.

is attached in the anchorage portion of the appliance in front of the irregular tooth, and is made to extend backward, following the gum line to the distal part of the molar to be moved, where it is bent forward on itself to form a loop, with the end resting on the grinding surface. A spring of this shape will not slip toward the gum as force is applied for moving the tooth outward.

When the arch was expanded sufficiently, the lower incisors were depressed in their sockets through the force of occlusion and by means of an appliance worn in the upper arch. (Fig. 15.) The appliance was made with a palatal base-wire anchored in the usual manner. To the anterior part of the appliance

back of the incisors was attached a semi-circular piece of plate metal, similar to the one described in Fig. 8. It was arranged to incline forward, and was supported against the upward thrust of the lower incisors by two small loops of spring wire, arranged to hook over the cusp of each of the canines. The ends of the wire extended below the table to which they were soldered.

Underneath the table and resting near the gum were two finger springs for moving the upper incisors outward. They were soldered to each side of the anchorage portion of the appliance, and made to extend forward in the direction of the lingual faces of the incisors to the opposite side of the arch.

When the lower incisors were sufficiently depressed, the finger springs were

FIG. 16.

bent forward slightly from time to time, in order to move the upper incisors outward (Fig. 16), after which the upper and lower arches were equalized to improve the occlusion. The same appliances were used for equalizing the jaws. For this a wire was extended from the anchorage portion of the upper appliance on each side of the arch, passing over the occlusal surface at the junction of the lateral incisor with the canine to the gum line, where it was soldered to a narrow partial clasp resting in front of the canine; at the same time a wire hook was attached to the partial clasp for holding one end of a rubber equalizing band. The other end of the equalizing band was supported by a similar hook attached to the distal part of the apparatus

on each side of the lower arch. When the apparatus is not well retained by the spring-clasp attachments, it is an advantage to cement to the last lower molar on each side of the arch a collar with a small lug on the bucco-distal surface, and attach to the anchorage portion of the appliance a wire clasp,

FIG. 17.

so shaped as to pass back of the molar from the lingual to the buccal side, resting under the lug, the spring terminating in the form of a hook. (DENTAL COSMOS for 1906, vol. xlviii, p. 282.) Fig. 17 illustrates the present condition of the occlusion, the regulating not yet

FIG. 18.

being completed. Six visits were required for adjusting the apparatus to bring about these changes. A local dentist under my direction added force by bending the springs occasionally.

Fig. 18 illustrates an appliance used for depressing the lower incisors, and

moving outward the upper incisors for a patient sixteen years of age. The appliance was similar to the one last described. The upper and lower first bicuspids had been injudiciously removed by another practitioner. The features were not sufficiently prominent, requiring the

nathous condition had resulted, the lower incisors biting near the gum in front of the upper ones. The bite was opened and the lower incisors were moved backward, after which a chin-cap was applied to force the jaws together and to adjust the occlusion. (Fig. 20.)

FIG. 19.

FIG. 20.

FIG. 21.

FIG. 22.

incisors and canines of both arches to be moved forward, and the spaces artificially filled.

I have used apparatus for opening the bite in a variety of cases, but owing to lack of time, will merely mention one or two additional cases.

Miss S., fifty-one years of age. (Fig. 19.) The early regulation of the teeth had been neglected, and an extreme prog-

Mrs. M., thirty-six years of age. An appliance was inserted in the lower arch to open the bite and move the incisors inward, and another one inserted in the upper arch for moving the incisors and canines outward.

Another similar case, that of a girl thirteen years of age, is illustrated in Figs. 21 and 22.

In concluding my paper, I will briefly

describe an interesting case of prognathism in a child aged two years and ten months. (Fig. 23.)

The mandible was very prominent, the incisors and canines touching the gum in front of the upper ones when in occlusion. The upper incisors needed to be moved outward, requiring the opening of the bite. The irregularity was successfully corrected by the application of a small metal inclined plane. The inclined

FIG. 23.

FIG. 24.

plane pointing backward was attached to the incisors and canines of the lower arch. (Fig. 24.) This had the effect of opening the bite and at the same time of forcing the jaws and teeth of the lower arch inward, and the teeth of the upper arch outward.

The inclined plane was made by joining two pieces of plate gold. A piece of soft wax was first molded on the lingual side of a cast of the lower incisors and canines, the surface of the wax being shaped to project upward and backward in the form required for the inclined plane. An impression was then taken of the labial faces of the incisors and ca-

nines, including the front and upper surface of the wax. From this impression a die and counter-die were made of fusible metal. A piece of gold plate was then swaged to fit the parts forming the front of the incline. The wax was then removed from the lingual side of the teeth, the plate of gold being held in proper position while another impression of the lingual side of the teeth and the projecting plate metal was taken with moldine. The gold was then withdrawn, and the moldine impression removed, after which a die and counter-die were made, and a plate metal was swaged to fit the lingual side of the teeth, projecting upward to join the piece of plate metal fitting the front of the teeth. The two pieces of plate were

FIG. 25.

united with gold solder, and thus an inclined plane and cap were formed. The cap was then roughened on the inside, and cemented over the incisors and canines with zinc oxyphosphate.

The device was applied February 10th, and on May 7th it was removed. The natural force of occlusion had corrected the conditions, as shown in Fig. 25, there having been no special discomfort experienced by the patient. The teeth were retained by the occlusion itself.

Apparatus for opening the bite should not be worn longer than necessary. The opening of the bite in any manner beyond the normal, if continued for a considerable length of time, is likely to prove detrimental to the occlusion. In opening the bite, the muscles are necessarily put on a stretch, and the teeth resting in contact, gradually become depressed in their sockets through the force of the occlusion, owing largely to the tonic contraction of the muscles.

THE EXTRACTION OF TEETH A SURGICAL PROCEDURE.

By **MORRIS I. SCHAMBERG, D.D.S., M.D., New York City.**
PROFESSOR OF ORAL SURGERY, MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA.

(Read before the First District Dental Society of the State of New York, at its monthly meeting, October 9, 1906.)

WHILE considering the selection of a subject that would interest the members of the society to the greatest degree, it occurred to me that while dentistry has advanced in many

and for that reason I chose the topic announced.

I do not wish to cast any reflection upon the specialists in the large cities throughout the United States and other

FIG. 1.

Radiograph of entire side of a jaw, showing a small piece of a retained end of a root requiring a surgical operation to effect its removal. The root has migrated to a point beneath the inferior dental canal.

respects, there was one particular branch to which had not been accorded the care and attention that it justly deserves,

countries who have adopted modern methods, and who are doing good and conscientious work in this direction,

but rather wish to influence the larger proportion of men who practice the extraction of teeth, and who look upon it as an operation of very little consequence—one which may be done in a slipshod fashion, and which need not be given the care in asepsis and antisepsis that is applied to operations on other parts of the body. With that

FIG. 2.

A character of disfigurement that may follow the extraction of an abscessed tooth if the socket is not properly treated.

end in view it will be my purpose during the course of the evening to call attention to some of the graver complications that arise when precautionary measures are not taken. The lantern slides which will be projected upon the screen are mainly reproductions of radiographs of complicated cases in extraction, which will tend to illustrate certain points which it would be difficult to bring out verbally or in writing.

That dental, medical, and lay publications are reporting deaths from the extraction of teeth is familiar to you all. The very fact that patients do die during

or in consequence of tooth-extraction shows that the operation is one that is not devoid of danger, and one that should

FIG. 3.

An abscess about the root of an upper central incisor, showing the area to be curetted to prevent trouble after extraction.

be accorded a place among surgical procedures that have a mortality rate. Though death is the most dreaded result,

FIG. 4.

An interesting case showing the normal and abnormal healing of tooth-sockets. The unhealthy socket did not become well until a thorough curetting of the diseased area had been performed.

there are other complications or sequelæ which should be guarded against with equal vigilance. Long periods of suffering, the eventual loss of a portion of the jaw-bone, and facial disfigurement (Fig. 2) are among the conditions which

are familiar as evidences of careless methods in tooth-extraction.

FIG. 5.

Radiograph showing a healthy socket of a second molar, which tooth was unnecessarily sacrificed to permit the eruption of an impacted third molar, which, owing to the oblique position which it had assumed, will never be as valuable as its predecessor.

Before the treatment of the teeth, mouth, and jaws became a distinct and separate branch of medicine, it was the custom, as you well know, for sufferers

FIG. 6.

Encysted canine and supernumerary tooth, the removal of which entailed a surgical operation.

from odontalgia in any of its forms to seek relief at the hands of the local tonorial artist, who at the same time was considered an expert in cupping and leeching. Little was done to conserve these important organs of mastication, and only after dentistry had become well established did people begin to appreciate

the value of retaining their teeth. This laudable conservation of the dental organs has brought about the conditions which in extraction operations render the adoption of surgical principles necessary if after-troubles are to be avoided. In the early days teeth were removed upon the first indication of pain. Today it is almost unpardonable to extract a tooth for the mere purpose of relieving pain. Of course, in some instances there may be extenuating circumstances to render the sacrifice necessary, but modern methods

FIG. 7.

Radiograph taken after the removal of the encysted canine and supernumerary tooth.

of alleviating pain, coupled with a clear understanding of cause and effect as it applies to dental pathology, stamp such cases as exceptions to the rule.

In the early days little was known about asepsis and antisepsis, and in spite of the crude instruments used, complications were few. This can be explained by the fact that the old extractors were dealing mainly with simple extractions. They removed teeth whose crowns were not entirely lost through decay; whose roots were not enlarged at the end; whose pulps had not through putrescence set up periapical infection; whose peridental membranes had not become diseased, and the enveloping process of which had not lost its normal resilience through inflammatory change. Under such conditions the normal healing of the socket naturally followed in the larger proportion of cases. Today it is exceptional to find

conditions ideal for the healing of the socket. It therefore becomes necessary to adopt measures to prevent, if possible, post-operative disturbances, such as secondary hemorrhage, painful tooth-sockets, osteomyelitis, infection of the glands of the neck, necrosis, septicemia, and pyemia.

It is well to keep in mind that the extraction of a tooth is a bone operation, and that the utmost care is essential lest severe consequences follow. Patients should be aware of the trouble that may result through neglect of the mouth after any operation which entails the shedding of blood, and they should be instructed to return for treatment of the socket if it is in any sense diseased. Whenever a tooth is removed which has been the seat of suppuration, infection spreading through the wound created must be guarded against.

FIG. 8.

A third molar in the horizontal position which was removed under ether without disturbing the second molar.

Professor Robert T. Morris, in a paper which he read before this society a few years ago, referred to the frequency with which death follows the removal of teeth the seat of acute suppuration. These fatalities can be readily avoided if proper pre- and post-operative treatment of the mouth is practiced. Patients—especially of the poorer classes, who are suffering from malnutrition and filthy mouths, and whose systems are unable to resist infections which may lead to a fatal termination—must be subjected to a most thorough cleansing of the mouth before

anything of a surgical nature is done. It is just as important that antiseptic washes be energetically used prior to the extraction of the teeth, as it is to advocate their use subsequent to the operation, and this should be the practice even in the case of mouths that are considered clean.

FIG. 9.

An impacted third molar in the horizontal position which required a careful bone operation to release it without injuring or sacrificing the second molar.

All instruments should be thoroughly sterilized regardless of the character of the case upon which they are to be used. The surgeon who would employ a knife which had not been boiled, or which had been used on a previous case without having since been cleansed and prepared for the operation at hand, would be severely condemned even though the part to be incised was already infected.

In a paper on "The Etiology, Pathology, and Treatment of Troublesome Tooth-sockets," which I read before the Academy of Stomatology of Philadelphia in November 1904, and which was published in the *International Dental Journal* for April 1905, the after-care of the socket was dealt with in detail, so that I will not take up your time with a revision of that subject. I wish, however, to call attention to the fact that all infected sockets should be treated until the pus discharge has ceased, and until healthy granulations line the cavity vacated by the tooth. If this is not done there is danger of infected foci remaining and eventually causing further disturbance.

A NEW ADAPTATION OF THE MICROSCOPE TO DENTISTRY.

By SHIRLEY W. BOWLES, D.D.S., Washington, D. C.

(Read before the District of Columbia Dental Society, January 15, 1907.)

THE object of this paper is to present to you a new microscope for use in the mouth. So far as we know this instrument is the only one that is adapted to our work.

My attention was called to this microscope by Dr. David Fairchild, who is in charge of "foreign exploration" in the Bureau of Plant Industry, Department of Agriculture. In setting forth the features which make it possible for the dentist to use it, I can do no better than to read a letter from Dr. Fairchild on the subject:

1331 CONNECTICUT AVE., N. W.,
WASHINGTON, D. C.,
January 10, 1907.

DR. SHIRLEY W. BOWLES, Washington, D. C.

Dear Dr. Bowles,—Having worked together as we have done upon the adaptation of the Greenough dissecting binocular microscope for dental work, I send you as my contribution to your paper on the subject a few suggestions, which indicate the way this investigation was started.

For over a year, ever since the first time that I looked through this new instrument, its possibilities in dentistry have impressed me. I have spoken to several dentists about it at different times, but never succeeded in arousing their interest in it until last summer when I described it to you. Finding that you were ready to look into its peculiar fitness for adaptation to your profession, it has given me the keenest satisfaction to work out with you the designs for a proper stand, by means of which this new microscope can, I believe, be of the same great aid in dentistry that it has proved to be for botanical investigations.

The facts that led me to believe that this remarkable new microscope was fitted peculiarly for dentistry are the same which have made it of such unusual value in the profession with which I am officially connected.

A comparison of this new invention with

the ordinary microscope will prevent those who would be so inclined at the first mention of the use of the microscope in dentistry, from pigeonholing the idea as something which is not new.

This is an entirely new and original type of microscope that has been on the American market less than three years, and I feel safe in saying that this is the first time it has ever been applied to the practice of dentistry. It is the invention of an American biologist by the name of Greenough, and was worked out in the famous microscopic establishment of Carl Zeiss at Jena, Germany, which firm is the only one that now manufactures it. It is a dissecting microscope, and does not invert the image as the ordinary microscope does; in other words, you can work with your instruments under it without learning that in order to touch a spot in the right of the field you must move your hand to the left instead of to the right, as you would naturally do. This one difficulty in the old type of microscope has effectually barred it from use in the mouth.

It is a binocular, and at the same time a bi-objective microscope. The old binocular microscopes were none of them bi-objective—that is, none of them had two objectives. The Greenough is essentially two separate microscopes fastened together in such a way that they give stereoscopic vision. This stereoscopic vision is one of its most remarkable features, and makes it rank beside the oil immersion objective as an instrument of research. I think that this character of the instrument will appeal to all in dentistry who are familiar with the ordinary microscope, and who know how shallow is the layer of any object which is in distinct focus at any one time. By means of the two separate objectives Greenough has overcome this difficulty to a large extent, and objects which under an ordinary microscope can only be seen in sections by focusing down from the top, are under this marvelous new instrument visible in their entirety. In dental examinations this feature is of the very first importance, because it is the relation of the form and size, rather than the character, of

a flat but small section of a cavity, that is important.

The instrument has the most remarkable "working distance" of any microscope known; in fact, this point alone is what at first attracted my attention to its possibilities in den-

electric light and a reflector that throws a beam of light on the precise spot that the objectives are focused on, thus illuminating it perfectly. The eyepieces are quite as adjustable as are those of the Zeiss field-glasses, so that by moving them back and

FIG. 1.

tistry. With objectives that magnify from eight to sixty-five diameters—that is, which are four to thirty times as strong as the hand magnifiers that dentists usually employ—a distance of from an inch and a half to four inches intervenes between the objective and the teeth. This distance is enough to allow any of the ordinary dental instruments to be used.

There is attached to this microscope a small

forth the fields of vision can be made to appear as one single field.

The instrument is light and easily manipulated, requiring little of the technique which the old microscopes demanded, and already it has entered the field of the plant-hybridizer, and is being used by gardeners who never in their lives saw through the ordinary microscope.

In botany—especially in the study of plant

diseases—it has quickly become invaluable: while in metallurgy, zoölogy, and in many other branches, it is rapidly becoming quite as necessary an instrument of research as is the old microscope. It has revolutionized the study of corals. I am informed, and the entomologists say that it has revealed entirely new characters in insects.

it one of your diabolical instruments to ascertain whether or not the nerve is exposed.

Yours very sincerely,

DAVID FAIRCHILD.

Owing to the impossibility of having the proper light in this room we could

FIG. 2.

I believe that could we get the instrument in position to look into the mouth of a patient in the chair, its own wonderful revelations would win for it the place it deserves to occupy in the art which of all others demands attention to the minutest details. In our joint designs for a stand to hold this instrument, I think we have been in a measure successful, though I trust important improvements will be made in it.

You will find its weak points by practice, but I cannot help feeling that it is to play an important rôle in the future of scientific dentistry. As a representative of that large and silently suffering class, your patients, I trust the time is not far distant when you will look into a cavity before you thrust into

not exhibit the microscope to you to-night. In lieu of that, Mr. President, I will hand you a half-dozen photographs which will show the microscope in focus upon a patient in the chair. These photographs also show the standard which has been constructed to carry the microscope. It rests on a heavy metal base, which is so substantially built that it is rigid enough to keep the instrument in focus. It permits of eight movements, enabling a perfect focus to be easily and quickly obtained. When the focus is once obtained, the horizontal arm can be

swung entirely free from the patient and returned to the same focus at will. When all set-screws are tightened, the operator can rest the forehead against the eye-pieces, leaving both hands free for work if desired.

I wish to call your attention in the pictures to the "working distance"—that is, the distance of about five inches between the nearest point of the instrument to the patient and the cavity or teeth in focus. This is one of the main points which is particularly useful to us. Another strong point in its favor is that the image is not reversed. These two extraordinary attributes permit the use of instruments which are magnified as well as the tooth, and actual work upon the teeth can be done under it if desired.

The last important point is the depth of the layer which is in focus. What this last point means can be illustrated by the case of a lower second molar from which the pulp had been removed. Access to the pulp-chamber was afforded through an occluso-mesial cavity. The canal in the posterior root and one in the lingual portion of the anterior root were easily located. It was believed that a canal existed in the buccal portion of the anterior root, but it could not be found with a broach. The microscope was then focused on the tooth, and the first look was a revelation. The whole tooth was in focus; not only this, but the entire extent of the cavity. It was quickly discerned by the formation of the dentin in the region of the suspected canal that one had existed, and a little drilling opened into the canal and a considerable portion of pulp was removed. The microscope had rendered the operation quick, easy, and precise.

The instrument is invaluable in finding exposed pulps without shocking the patient by using broaches and explorers; also, in lifting out partially decalcified dentin, which comes away in a leathery mass from deep cavities, it will prevent injuring the pulp. When a pulp is nearly exposed, it will quicken our judgment as to whether dentin should be left to recalcify. By using this microscope after a cavity has been prepared, any softened

structure which has been left can be detected, and weakened enamel prisms may be clearly distinguished. It is like proving a mathematical problem, and removes most of the uncertainties of cavity preparation.

Many difficult features of a critical examination of the mouth are minimized, if not entirely cleared away, by the use of this microscope. It can be clearly seen whether discoloration around a filling is due to faulty margins and recurring caries or whether it is caused by staining of tooth-structure by the filling material. Imperfect margins can be seen when an explorer passes over them, and small approximal cavities can be found in interdental spaces where it is impossible to pass an instrument, and where a slight separation is necessary to make sure the presence of a cavity. More than this, in interdental spaces where instruments can pass and detect nothing, the microscope will reveal areas in which the cement substance of enamel rods has been dissolved in the first stage of enamel caries.

By the use of the electric illuminating apparatus, observation can be made on the molars nearly as perfectly as on the anterior teeth. For the distal surfaces of molars it is of course necessary to employ a plain mouth-mirror in order to secure the image upon which to focus.

Professors and demonstrators of operative dentistry would find this microscope a wonderful assistance in the teaching of the branch. The present method in vogue is most excellent, but its one weak point is a flagrant one. It is this: Students obtain their first knowledge of cavity preparation from large technique models. The size of cavities prepared in the models are so out of proportion to the same class of cavities in the mouth, that the first work of students in the infirmary is apt to be destructive of good tooth-substance. Now, if a student could see a properly prepared cavity through the microscope, and have the salient points clearly shown, it would undoubtedly go a long way toward overcoming the embarrassment now experienced, and would benefit both student and pa-

tient. Besides its unique possibilities in the mouth the Greenough microscope is specially adapted to research work in the dental world.

The apology, and no paper is complete without one, is that we cannot present more complete data, but the adaptation of the instrument is young and its use not

perfectly regulated as yet. The hope is that this paper will create an interest in this new acquisition, and that many investigating minds will adopt it. The belief is that its use will open up new avenues of research, and be an immense contribution to exact methods and scientific dentistry.

A REVIEW OF THE METHODS EMPLOYED FOR THE RETENTION OF FILLINGS.

By H. HERBERT JOHNSON, D.D.S., Macon, Ga.

(Read before Section II of the National Dental Association, Atlanta, Ga., September 18, 1906.)

BEFORE proceeding with the main subject under consideration, I wish to explain that while the subject-matter of the paper will of course deal largely with contour gold filling, I would very much dislike to have it construed for a minute that I advocate, even to a small extent, a useless display of gold in teeth. On the contrary, I look upon it as most reprehensible, and advocate and practice the filling of all incipient cavities of decay from the palatal and lingual surfaces where possible. With my efforts constantly directed to the accomplishment of this purpose—endeavors extending over a long period of practice—I have found that it is possible in over fifty per cent. of the cavities occurring in the six anterior teeth. It is hardly necessary to further state, except in defense of my proclivities for progressiveness, that I am not unacquainted with porcelain work and all methods of burnished gold work, as cast fillings, hoods, staple crowns, etc.

I fully recognize that all of the newer methods alluded to must be practiced by everyone who would render the best service possible to his *clientèle*, as we have not yet reached a point where we will not occasionally find a use for contour gold filling, even though we recognize and regret the objectionable display of gold.

It is my belief and I think I can show conclusively, that the methods of preparing cavities for the reception of the filling material, not only in these display fillings but in many of the other class, have in the past been attended with a needless destruction of strong sound tooth tissue, which could not only have been avoided, but by the employment of other systems greater strength of retention could have been obtained. To make my argument, if possible, more convincing, I wish to submit for your consideration a partial review of methods of retention as advocated and practiced by some of the leading operators and writers of modern times.

During and since the days of Marshall Webb, the best operators and writers—including Webb—have almost unanimously advocated for the retention of gold contour fillings, especially in incisors, either cutting a step taking in one-half or two-thirds of what is left of the incisal edge of the tooth (see Figs. 1, 2, and 3), or cutting what is usually termed a doll-head or arm on the palatal side, near to the cutting edge, extending quite two-thirds across the tooth, involving all of the enamel plate and nearly the entire thickness of dentin. (Figs. 4, 5, and 6.) Even the advocates of these proce-

dures have admitted the weakened condition resulting from the cutting of the dovetail or doll-head on the one hand and the increased display of gold from the cutting of the step on the other.

Dr. C. N. Johnson, in a series of very ably written articles running through volume xl of the *Cosmos*, presents on page 813 (figures "10" and "12") illustrations of a method which he advances for the retention of these large fillings.

weak support this method gives to the filling can readily be observed by the practical operator.

Dr. M. L. Hanaford, in an article before the Illinois State Dental Society on the "Preparation of Cavities," published in the *Dental Review*, vol. xii, page 681, says, "The third type of cases includes those cavities in which caries has progressed so far toward the incisive edge as to render unsafe any undercutting for

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

Of course by this method he prevents, for the time being, the extra display of gold which would be occasioned by the step-cutting (see Fig. 3), and anticipating the crumbling, removes entirely the weakened lingual wall of enamel that is left in the cutting of a doll-head retainer. (See Fig. 5.) But it is very plain to even a casual observer that he has left a very weak, partially unsupported wall of enamel on the labio-incisal edge of the tooth.

In the "American Text-Book of Operative Dentistry," edited by Dr. E. C. Kirk, we find on page 192, in a strong article by Dr. S. H. Guilford on "Cavity Preparation," the illustration as seen in Fig. 4, where he extends an arm on the lingual surface, which he recommends to be cut but little deeper than the enamel. The

retention at this point, but where, for esthetic reasons, it is desirable to retain the labial plate of enamel. In such a

FIG. 7.

case the lingual plate is removed for a sufficient distance from the incisive edge root-wise, and extending into the body

of the tooth far enough to make possible a step. This is deepened at the extrem-

FIG. 8.

ity, squared, and made retentive." (See Figs. 1 and 2.) This suggestion of Dr.

the pulp-chamber and pulp-canals. (See right side of Fig. 8.)

I feel that it is hardly necessary to go farther into a review of such methods, as I believe these few will suffice to establish the fact that they constitute the prevailing methods of retention of this class of fillings, if indeed, there be anyone who would be prepared to deny it at all. I also believe that all will admit that in these methods there is necessarily a great sacrifice of sound tooth tissue, and in some instances a great display of filling from excessive cutting.

The only other means heretofore brought forward to improve these de-

FIG. 9.

Hanaford is clearly after the method of Dr. Johnson, as can readily be seen by comparing the two systems.

In this connection I would also refer to the idea advanced by Dr. Weld of New York, published in a leading text-book. This method is illustrated in Fig. 3, compared with that advocated by Henry Sewell, M.R.C.S., L.D.S., of England. (See Fig. 7.) Dr. Sewell's method would have the advantage from an esthetic point of view, but would be at a disadvantage as to strength of retention.

In *Items of Interest*, vol. xxvi, page 130, appears an article by Dr. Hanning, read before the Second District Dental Society of the State of New York, in which he advocates a kind of post retention for these display fillings. This idea, however, seems to be limited to those devitalized teeth where use can be made of

structive methods—at least the only one which has come to my knowledge—is the little anchor screws sold by The S. S. White Dental Mfg. Co. and illustrated in Fig. 9. These screws have been used to a limited extent in very favorable cases, but they have never been popular on account of the clumsy size, and the difficulty in securing the accuracy necessary for their adjustment, as they depend on the holding power of the threads in the dentin for support. They also require a hole to be drilled, the size of which weakens the body of the tooth very materially.

As a general substitute for all these methods of preparation of cavities and retention of filling, and especially those contour fillings involving the restoration of the corners of incisors, I wish to offer the following idea, which if not new, at least possesses some novelty, and which

has not thus far, to my knowledge, been illustrated or published; it has in its favor the essential points of being extremely simple, strong, and practical: Instead of cutting away so much strong

num wire, No. 20 gage or smaller, according to the size and thickness of the body of the tooth.

To give them an increased holding power, they are barbed on the edges, bent at an angle, and flattened at the end that is to be embedded into the body of the filling. Being thus flattened—which is quickly and neatly done by crushing with a pair of strong pliers—it will be readily observed by studying Fig. 13 that the bulk of the metal of the stay is all there for strength, and yet the flattening process has given it such shape that the strength of the gold has been but little impaired by having it thus flatwise embedded into it. The little wire stay can be easily adjusted, even in narrow spaces, by taking care to carry it to place with the flattened end projecting either labially or lingually, until it is pushed clear up into the previously drilled hole, and then turned downward until it assumes its correct position, as is seen in Fig. 12.

FIG. 10.

FIG. 11.

enamel and dentin in the formation of the steps for anchorage, it is only necessary to remove all weak walls, clear out the decay, and polish the margins of the enamel. Next make a slight groove, undercut, or any other shaping desired, at the approximo-gingival margin of the cavity, from which to begin the filling. At the incisal edge take a very small round bur—about No. $\frac{1}{2}$ of the “revelation” type, and bore a hole into the dentin between the two plates of enamel. Begin at the extreme incisal edge of the cavity, and proceed downward and backward approximately at an angle of about forty-five degrees, just missing the posterior horn of the pulp. (See Figs. 10 and 11.) Extend this hole deep enough, using judgment in each case, to give firm anchorage for the little iridio-platinum retainer which is to be cemented into it. (Figs. 12 and 13.) These little stays are preferably made of squared iridio-plati-

FIG. 12.

FIG. 13.

These little wire retainers are exceedingly strong, and will stand an enormous amount of force. By their use we sacrifice a minimum amount of valuable tooth tissue, reduce the display of gold to the

smallest possible, and also get a much stronger anchorage for the filling. They are applicable to many other classes of

In Fig. 15 the application of the gold is shown, half built in, about the retaining wires seen in Fig. 14.

FIG. 14.

FIG. 15.

FIG. 16.

cavities, as will be readily suggested to the practical mind. The simplicity of making and adjusting appeals at once to the progressive reasoner.

A suggested application is further shown in Fig. 16 which might extend the field of usefulness of these stays beyond that already demonstrated.

THE F. D. I. COMMISSION ON HYGIENE.

By Dr. LYMAN CURTIS BRYAN, Basel,

PRESIDENT OF THE SECTION OF HYGIENE AND PUBLIC DENTAL SERVICE OF THE F. D. I.

(Abstract of address delivered at the F. D. I. meeting at Geneva, August 1906.)

THE work of the Commission on Hygiene and Public Dental Service should be the most important and useful to humanity of any of the commissions of the F. D. I., and should have the support of every member of this great International Federation. The work of attending and treating the needy poor is one which should appeal to every man with human and charitable instincts, and should not only interest the dentist, but also appeal to every human heart. There is not one of us who has not felt the pangs of regret that there is so much dental work to be done in the world, and that there are comparatively so few to do it, and worse still so few who appreciate it. Not but that there are plenty of den-

tists to do thorough and conscientious work for the favored few, but where is the host that is to work for the millions of needy human beings who have neither the opportunity nor the means to have their dental work done, even if they have the inclination?

In my hospital dental work in Basel I found that the public was not prepared for conservative dentistry—that is to say the class of people, the servants and laborers and lower classes, who came to the infirmary and the dental clinic only came to be relieved of their present sufferings; and even where the work was gratuitous they would allow nothing to be done, as a rule, for those dental organs which did not at the moment cause incon-

venience and pain. I am convinced that even if dental services were furnished gratuitously by the state, a very small portion of the needy poor would apply for conservative dentistry. Either the pain connected with dental operations is sufficient to frighten away the ignorant, timid, and improvident lower classes of humanity, or they do not appreciate the value of teeth in good order, having never possessed such from youth up. Those who have had experience with the country people in the farming districts of Switzerland tell me that there is absolutely no demand for conservative dentistry among these people, and that all they require, as a rule, is to have teeth extracted and replaced by artificial ones.

Not only is this the case in Switzerland and among the poorer people, but it is the general demand in many countries, according to information furnished me by members of this association who come from all parts of the world. Therefore I hope that you will discuss very carefully and conscientiously the first question which I have submitted for discussion on the program of this meeting, viz:

How shall we reach, interest, and educate the public in dental hygiene?

Before the dentist could commence conservative dentistry for the needy public, there is a great work to be done in educating the poorer classes in the personal care of their teeth. To attempt to do our delicate and complicated operations for patients who have no habits of dental cleanliness would be most ill-advised charity, and before we can help this class they must be taught their own duty to themselves, and my opinion is that our efforts should be directed almost entirely to the rising generation. The work before us is of such gigantic proportions and the means at our command are so limited and the workers so few, that we will have to be content with small beginnings and be satisfied if in the next few years we can secure in every large city of the world a school dental clinic for the younger—the very youngest—of the coming generation. Beginnings have already been made in this direction in various countries; probably the greater achieve-

ments have been accomplished, and the ground broken most thoroughly in preparation for this great work of bringing up the children in the way they should go, in that great progressive country north of us, united Germany. Here we see Strasburg to the front with its wealth of experience in experimental ways, and the man who has done the pioneer work so successfully, Professor Jessen, who is with us today, will give us most valuable information and the results of his labor and experience. I am sure we will all take home with us from his lecture many valuable points for our guidance in establishing school dental clinics in various parts of the world.

Professor Jessen is probably the man who can best answer our second question, viz:

How should the school children be treated to assure a useful dentition through life?

There are many others here and many others not here who are in sympathy with us, who have given much thought and attention to this question. This is really the greatest question before us. I am exceedingly disappointed not to be able to present for your consideration the thoughts and suggestions of the officers and members of this commission in various countries, but my appeal by circular letter to the members for information has not brought one essay or paper in advance of this meeting which would be a guide and help to me in addressing you today. There are ready, however, a few considerations, reports from various countries to be made by the delegates themselves, and I am sure that with all the earnest workers that I see about me there will soon be the dawning of a bright day for public dental service throughout the civilized nations of the world.

Let us all go earnestly to work and let every delegate here make a beginning in his own country to interest the people in public dental clinics. Let us show them what has been done in other cities and present to them statistics of the good work already accomplished, and stimulate national and local spirit to undertake similar charitable work and contribute

generously with financial support; but above all, let us through our local dental societies awaken an interest in the public and educate them to appreciate what we desire to accomplish. The work we do in this international commission—and in fact all the work of the Federation—is advisory; the actual work must therefore be carried out by the dental societies in the various countries, and it is our duty as members of this commission to see that our national and local societies take the necessary steps to bring the results of our discussions and the conclusions reached by the delegates from all countries here assembled, and working in the interest of humanity without national or local prejudices, before their governments and other bodies who should take action in the interests of the suffering poor.

I believe we shall be able to convince the most skeptical and parsimonious government official that it is for the national good and is necessary for the national physical development that the teeth of the rising generation be most carefully looked after, and that public clinics for this purpose should be carefully organized and generously supported, should be provided with thoroughly equipped instrumentaria and the work be done by thoroughly educated dental surgeons, not by students or by men not specially trained in dental colleges or dental departments of universities. We should be able to convince them that this work is more important than any other prophylactic or hygienic measures already undertaken and under government supervision for the welfare of the public. We are all convinced, as dental surgeons of experience, that the money invested in providing healthy mouths in the rising generation and instilling in the public mind the principles of personal dental hygiene will be saved tenfold in money now invested annually in general hospitals and other sanitary institutions where the diseases treated can in a large proportion of cases be traced directly to malnutrition, infection, defective assimilation, nervous and other disorders resulting directly from defective dentures.

All countries have recognized their duty to care for the suffering poor, and are spending millions in treating the after-effects of human diseases resulting in many cases directly from bad teeth and diseased mouths; whereas, if thousands had been spent in caring for these mouths early in life, these diseases and the resulting suffering would have been spared and the usefulness of thousands of citizens greatly enhanced, not to mention their freedom from local dental pain.

It is the universal opinion of those best able to give an opinion that money invested in school dental clinics by the government is the best investment that can be made for the health of the people, and that dental treatment early in life prevents more diseases in after life than any other prophylactic measure taken by governments, not even excepting vaccination.

Therefore let us present these facts to our respective governments and suggest early action and a trial of a school dental clinic for the primary classes, as the most advisable and reasonable beginning of this great work that is before us. We are convinced that the school in early life is the only place to begin this work, and that on the basis of results here achieved the greater work can be planned and gradually extended. Let us not undertake to commence more than this elementary work, which, in the present state of governmental indifference and public ignorance of the crying necessity of this long-neglected branch of public hygiene, is all we can hope for or accomplish.

I am of the opinion that our third question—

How shall the needy public be treated?—can only be answered by saying, "Let us relieve their present sufferings as speedily as possible in our private clinics or by securing the appointment of dental surgeons in the hospitals, and demanding in every public hospital a dental surgery where those not actually confined to bed or those convalescent can be conservatively treated and their mouths put in order before they are discharged from the institution as cured and as prepared to undertake life's arduous duties again." Let us insist, through our local dental

societies, on this first step being taken by those in authority, and this beginning will sow the first seeds in the best of soil.

The gratuitous distribution of tooth-brushes in the schools and the examination of school children's teeth has been so thoroughly discussed and unanimously approved by this International Dental Federation that the far-reaching advantages of these preventive measures may be considered as an established fact.

The publication and distribution of a booklet on dental hygiene by the national dental societies or under the supervision and authority of the Federation is a subject which should occupy your very care-

ful consideration, as well as the establishing of a definite plan of work for the commission.

Now that we are to have regular annual meetings of the Federation, we should plan our work so that the results of our conferences and the conclusions reached will bear fruit in the various countries whose delegates attend this congress. It is only through them that we are to accomplish the results that the Federation is striving for, and my last word to you is an appeal to one and all to use his personal efforts *at home* that the work done here may not lie a dead letter in the archives of the Federation.

THE REPAIR OF PORCELAIN FILLINGS.

By JOSEPH HEAD, M.D., D.D.S., Philadelphia, Pa.

(Read before the Reading, Pa., Dental Society, February 7, 1907.)

MANY conscientious porcelain workers declare that porcelain fillings should not be repaired. To patch them, they say, is a confession of failure—an admission that the operator was not able to carry out his original plan—and therefore the chipped filling should be replaced with a new one. This is the rather severe attitude of a stern idealist who sticks to principle through everything, and as such these opinions should receive sympathetic and respectful consideration. It is unquestionably true that a patched porcelain filling is not so perfect and beautiful a piece of work to examine critically as a perfect one. Such a filling when viewed closely is in no danger of passing unnoticed, and so is not *per se* so artistic. This admission, however, cannot be held as a final condemnation of the practice of repairing porcelain restorations. On the contrary, the vast majority of chipped porcelain fillings can be so successfully repaired as

to be still unnoticeable to the general observer.

So the proposition resolves itself into two questions: Are we to be exact copyists of nature in every detail—like for instance the great artist Meissonier? or are we to be impressionists who only care to give the impression of perfect teeth to the outside general observer? We must remember that the impressionist may be equally true to an ideal when he feels that so long as our fillings look well from outside of the mouth, it is a question of indifference how they appear when examined by the mouth-mirror, if they are wholesomely preserving the teeth and performing their proper functions of mastication and interdental space protection.

It must also be remembered that we owe ideal justice to our patients, and we should not compel them to undergo the pain and expense of new fillings unless they are going to be reimbursed by receiving practical benefit. I would not be

understood as decrying ideals; dentists cannot do good work without them; no work can be too artistic or too good; but let our ideals be practical. If an inlay cannot be inconspicuously patched so as to be sightly, strong, and tooth-saving, it should be replaced with a new one; but where a few minutes' work will make the filling as good if not better than before, it is ridiculous not to choose the lesser operation.

The one great objection to porcelain work lies in the fact that porcelain edges will chip when they are exposed to the direct force of the occluding teeth. There are but two ways of meeting this difficulty: One is to place the edge so as to avoid such occlusal shocks; the other is to boldly mend the edges when they crumble. The former cannot always be successfully done, but the mending can be accomplished in such a way as to make the fillings more likely to last than before the fracture occurred, which is not the case when an ordinary gold filling is repaired. For when decay sets in around a hammered gold filling, the microscopic spaces that usually occur between the metal and the tooth may lead the decay from the margin directly to the bottom of the cavity. Thus in cutting out the spot of decay and filling it up with gold, there is no real security that caries may not have been left underneath. But with an inlay we know that the defective edge with its consequent decay does not extend below the hard cement. So having cut to that decay we can fill the defective line in perfect security that no infection has been overlooked. It has been proved conclusively that a one- to two-pound blow delivered on the edge of a porcelain filling by an occluding tooth will chip or powder the edge. There is a possibility of such an accident any time we eat. On the contrary, gold or amalgam flow before the force of percussion. If, therefore, we could combine the plasticity of these metals with the hardness and beauty of the porcelain we could have the almost ideal filling. And this is what we do, to a large degree, when we mend chipped porcelain with gold or amalgam; for with an edge so mended the force of mastication tends to hammer the gold into the

edge and make it more perfect, rather than tending to cause a recurrence of the trouble.

The method of procedure is as follows: Cut out the defective line with a small inverted cone, cutting in the direction of the tooth rather than the porcelain. Dry the cavity with alcohol and hot air. Have moss fiber gold, properly annealed, in small pieces, near at hand. Mix some creamy cement, place it in the cut-out groove, and squeeze this cement out with suitable pieces of moss fiber gold, being careful to remove all excess of cement. When the cement has set, condense the gold and finish in the usual way with either hand or mallet. If amalgam be used the procedure is practically identical, only the cement is squeezed out with the amalgam instead of gold, and hardened by wafering in the conventional way. And let us note an advantage for this method that has not perhaps been given its just due: When a gold or porcelain filling is cemented into place the entire cement line is just as large as the largest grain of cement powder in the mix. But with gold or amalgam flowing around the few large grains, the cement line becomes almost imperceptible.

The places most likely to need mending, as before stated, are those that receive the direct force of mastication, such as the grinding surfaces of molars and bicuspid. The fillings on the labial aspect of incisors, canines, and bicuspid are not subject to such stress and therefore are not likely to need mending. But with these in a certain percentage of cases a black line will appear. This, from the very fineness of the cement line, is most difficult to remedy, but it may usually be accomplished in the following way: Put on the rubber dam. Wash the dark line with alcohol and afterward with ammonia; dry with a hot air blast. Then flow 25 per cent. pyrozone into the darkened fissures and dry instantly with as hot an air-blast as the patient can bear. This will usually render a part of the line white and clean, when the pyrozone can be reapplied and the procedure repeated until the stain has been entirely

removed. The line can then be refilled with cement and the filling will be as good as new.

When porcelain corners of incisors chip on the cutting edge between the tooth-structure and the filling, leaving a little three-cornered nick, in the vast majority of cases a new filling will give the most satisfaction. But even these nicks can sometimes be cut out from the

back and filled as previously described, so that the small amount of gold that shows in front will be invisible from a distance of ten inches. This, from the impressionistic point of view, is all that is necessary; for, as a very bright young lady once said speaking of the fine gold line, if anyone gets nearer than ten inches, even then he is not likely to see it.

A SYSTEM OF UTILIZING ATMOSPHERIC PRESSURE FOR THE RETENTION OF LOWER PLATES.

By D. H. YOUNG, D.D.S., Attica, N. Y.

(Read at the November meeting of the Eighth District Dental Society of the State of New York.)

PHYSICAL science tells us that the atmosphere exerts a pressure of 14.7 lbs. to the square inch on all objects on the earth, our bodies included. Since the average man has a body surface equal to about 16 square feet, we find by multiplying 144—the number of square inches in a square foot—by 14.7—the number of pounds' pressure on each square inch—that it equals 2116 pounds, or over a ton, to the square foot; and since we have 16 square feet of surface on our bodies, the pressure upon each of us is over 16 tons. This gives us an idea of the strenuous life we are compelled to live. Such high pressure, however, is our birthright, and not our choice.

In this principle there is nothing new to us. We all familiarized ourselves with it when boys in school, and yet few realize that it is an ever-acting law of nature, which when brought under our control may be made to serve many desirable purposes.

It has been very successfully applied in the retention of upper dentures, which not so very long ago were held in position by springs; but it yet remains for us to

find out how we may best apply this force to the holding of the lower teeth in position. This brings us to the much-discussed subject of plates, but shall we not stand justified if by considering this subject tonight we may be able to help each other in solving this problem of lower plate retention?

Doubtless many have their own methods of securing atmospheric pressure on full lower plates, and some may never have tried it at all; so, in the hope of bringing out a discussion on the subject, I shall endeavor to describe a method which I have used for several years for securing atmospheric pressure on the full lower plate. For impression material I have used modeling compound—Perfection compound has given as good satisfaction as any. Plaster of Paris, of course, is an ideal impression material, but it does not give the kind of impression that is desired in this method.

The compound is warmed to a consistency at which it will adapt itself readily to the shape of the mouth, placed upon the tray, put in the mouth, and pressed down almost as far as you desire it to

go. Then wait for a minute or two until it hardens slightly. During this interval of time I have my assistant direct a current of cold air into the mouth from a rotary fan in the dental engine, which procedure chills the outer layer of the compound and prevents it from flowing away from the jaw when pressure is put upon it. While the layer of impression material that is in contact with the tissues is still warm and plastic, the tray is pressed down just a little farther, and then held steadily—with about half the force used in pressing it down the first time—until it is quite hard. The tray is then removed and the cast is poured.

In order that we may know why we proceed in this manner, let us go over the taking of this impression again. In the first place, when the material is put in the mouth and pressed down we get an ordinary impression; after it is allowed to stand a little while and the outside is chilled and pressed down a second time, the impression is changed from the ordinary one, but in what way? When pressing down on the tray the second time, the hard ridge of the alveolus cuts just a little deeper into the impression material, and remains practically unchanged, while the soft tissues down on the sides of the gums, about where the border of the plate comes, are com-

pressed slightly. When the plate is made on the model from this impression and put into the mouth, the margins of the plate are sealed all the way round, and this converts the whole lower surface of the plate into one great suction-pad—if we may use that term.

One of the most delicate parts of the operation is the trimming of the plate to just that line that will best seal its borders, for if it be too long it will give the muscles an opportunity to displace it; if too short it may allow the air to pass in, and thus defeat our whole purpose.

It is self-evident that the upper plate is retained by air-pressure against gravity, while the lower plate adds its own weight to atmospheric pressure; and so, compared with the upper, the lower has twice its own weight to add to the atmospheric pressure, thus showing that it is a better subject to be retained by such pressure than the upper plate.

The lower plate has always been a *bête noir* in dentistry. Of course we all would rather fill, treat, crown, or bridge to meet the conditions we find in the mouth, but occasionally there come before us conditions for which the science and art of dentistry has nothing better to offer than a plate. How necessary, then, both for the comfort of the patient and for our own credit, that it be made to stick!

PROCEEDINGS OF SOCIETIES.

NATIONAL DENTAL ASSOCIATION.

Tenth Annual Meeting, Atlanta, Ga., September 18-21, 1906.

(Continued from page 314.)

SECTION I: Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

Chairman—B. L. THORPE, St. Louis, Mo.

Secretary—D. O. M. LECRON, St. Louis, Mo.

FIRST DAY—TUESDAY.

THE first meeting of Section I of the National Dental Association was called to order by Dr. Burton Lee Thorpe, chairman, on Tuesday afternoon, September 18th, in the ball-room of the New Kimball House, Atlanta, Ga.

The first order of business was the reading of a paper by Dr. RICHARD SUMMA, St. Louis, Mo., entitled "Some Thoughts Concerning the Contact of the Teeth," as follows:

SOME THOUGHTS CONCERNING THE CONTACT OF THE TEETH.

Fallacious and indistinct conceptions have ever tended to enrich nomenclature. Unfortunately, words thus coined not only failed to elucidate, but, on the contrary, complicated matters. In nomenclature, just as in mechanics, simplicity follows the solution of a problem.

In the dental world the pathological condition most commonly known as pyorrhea alveolaris is an example of such an unsolved problem, whose many names bear evidence of an indistinct and fallacious conception. An epithet may offer some consolation and even satisfy the self-esteem of some writers, but it never adds one iota to the solution of any problem.

And so it is in regard to the contact of the teeth, both approximally and oc-

clusally, especially the latter. Hasty observation of the interdependence of the dental arches has prompted the necessity of a more or less complicated terminology to designate harmony and the various degrees of inharmony.

While in case of so-called pyorrhea alveolaris its obscure etiology and its varied manifestations may be responsible for the continued use of its superabundant names, such reasons no longer exist for the diverse employment of terms to express the contact of the teeth of opposing arches. Although the etiology of malposed teeth is as yet but imperfectly understood, we are so cognizant of sufficient facts concerning the contact of the teeth as not only to preclude the necessity of a complicated terminology, but to plainly indicate simplicity of terms.

We know that the teeth of man erupt to take their places in a fixed order. Thus no one doubts or disputes that it is normal for the central incisors to erupt on each side of the median line; adjoining these the lateral incisors, canines, first and second bicuspids, first, second, and third molars take their places. After recording this arrangement of teeth as the accepted one, I was just about to state that their approximal contact had never been an issue of dispute—when I became mindful of the discussion of Dr. I. B. Davenport's paper in 1887. (See *Cosmos*, vol. xxix, pp. 413, 445.) One

must read the entire discussion to fully appreciate the prevailing misconception at that time—for which Dr. Arthur's teaching appeared to be responsible—as to the scheme of approximal contact of the teeth. It seems that this article, entitled "The Dental Arches of Man," embodied the first ray of truth which penetrated the delusion of that day. He directed the eyes of the thinking dental profession to that scheme of nature which provides a methodical approximal contact of teeth. This fact led the same author to the realization that for the fulfilment of their function the teeth of one arch must come into contact with the teeth of the opposing arch in accordance with an equally formulated design.

To express the contact of the teeth of opposing arches Dr. Davenport uses the word "articulation." Numerous other words have arisen to designate this anatomical relation. Many of these resulted from a different significance attributed to this contact, and most of them were the outcome of the innate unwillingness of one author to subscribe to the diction of another. It matters little what we call this contact, whether it be articulation, occlusion, interdigitation, antagonism, mordex dentalis, odontarhosis, or green cheese, just so we understand the picture to be conveyed by the word. Since we must call it something, I hope that in the near future all orthodontists may see fit to adopt the word occlusion, also recommended by Dr. Guilford in a paper read before this association last year. (See *Cosmos*, 1906, vol. xlviii, p. 135.)

Not only did the naming of the contact of the teeth of opposing arches create much discussion, but authorities also found difficulty in agreeing upon a picture and an adjective to designate a contact which is according to the standard or rule that is observed or claimed to prevail in nature. Some doubt has been expressed as to the justification of denoting a certain occlusal contact as "normal," because the design of nature in many instances is obscure. Admitting the frequent difficulties encountered in drawing a line between health and dis-

ease or between normal and abnormal, I believe that such doubt in case of the occlusal contact of teeth is as groundless as a doubt in regard to their alignment in the arch would be. It is my opinion that natural selection, which prevails in every phase of nature, tends to reproduce organs best adapted for the performance of the functions demanded of them so that they may endure in the struggle for existence. It seems to me but logical to assume that the germs transmitted for the jaws and teeth in any given case tend to reproduce jaws and teeth primarily indicative of the genus to which the parents belong, and that they only secondarily impress upon these organs the family characteristics of the more immediate ancestors. Therefore we would expect to find in man jaws and teeth peculiar to the *genus Homo*, and varying within certain limits according to racial and family characteristics.

No one who has been in the general practice of dentistry for any length of time could fail to observe identical malposition of the teeth of parent and child. To what extent these cases are hereditarily transmitted characteristics, and to what extent the conditions are due to similar environments, is so difficult to decide that I have no desire to argue the question, but I wish to state my belief that the orthodontist's duty is plain in either case. He must strive to place these teeth into the occlusal relations which are normal for that type of the genus. It is well established that the teeth of all mankind are not only of the same pattern and alignment in each arch, but that an identical occlusal arrangement prevails with equal certainty. The variations consist in a slight difference in the curvature of the arches and a difference in the position the dental arches occupy upon the bodies of the maxillary bones.

Many discussions of orthodontic problems have been suggestive of the idea that for certain types of the *genus Homo* thirty-two is too large a number of teeth, and that crowding of these reveals, therefore, a plan of nature to eliminate excessive teeth, especially for the purpose of

improving the facial contour. If we stop to consider that utility is of first importance in determining everything of which we are conscious, the absurdity of this intimation becomes apparent. Beauty is secondary. We unconsciously accept as a standard of beauty that which utility inevitably forces upon us. Thus the African admires the prominent lower part of the face due to physiological prognathism. Prognathism with these people is a matter of utility. The Caucasian admires the facial contour resulting from orthognathism, which is also a result of environment, consequently a matter of utility, which thus creates a standard of beauty.

The dependence of facial contour upon the underlying osseous structure and the relative standard of beauty brings to mind the able article of Dr. Bebb, entitled "Disproportion in the Dimensional Relations of the Jaws and Teeth." (See *Cosmos*, 1905, vol. xlvii, p. 660.) He writes as follows: "If I interpret the orthodontists correctly, they would say the teeth of the bulldog are in perfect harmony with the supporting integument, only you must establish 'normal occlusion' by mechanical procedure, protrude the jaws and contract the arches until the teeth occupy their normal position, such as the conditions were before man interfered.

"The result would be what? A dog with body, limbs, and crania all in good proportion, and with a long, narrow snout, like a wolf or coyote.

"Shorten the mastiff's arches until this noble animal resembles an overgrown pug dog, and would you not arrive at the conditions which the orthodontists seek in the human?"

Dr. Bebb's misinterpretation, for such it is, seems to be quite prevalent. First of all, if an occlusionist were asked to suggest a means to improve a bulldog's denture he would certainly not think of reducing the protrusion of that freak's mandible. On the contrary, he would endeavor to exaggerate this unnatural protrusion in order to enhance the relative beauty of this degenerate. However, we must keep in mind that the bulldog is

not the result of natural selection, and this very feature of protrusion of the mandible at which the fancier aims would disqualify this poor freak to endure in the struggle for existence. The occlusionist is aware of the fact that the bulldog's relative beauty is enhanced in the same proportion as his ugliness increases and the usefulness of his teeth for the purpose of mastication diminishes.

Let us forget freaks, degenerates, monstrosities, etc., while trying to formulate a fundamental principle, and turn our consideration to the naturally selected and more important species, such as the mastiff. Again, the occlusionist would refrain from even an attempt to reduce the snout of a mastiff to that of a pug dog. He would endeavor to restore the dental arches to those positions upon the bodies of the maxillary bones which to the best of his knowledge are normal for that particular species.

In conclusion permit me to urge that not only should the orthodontists agree upon occlusion as the word to designate the contact of the teeth of opposing arches, but that this contact should be the basis of all their efforts.

Discussion.

Dr. S. H. GUILFORD, Philadelphia, Pa. Dr. Summa and myself agree on a great many points and we disagree on others. He belongs to what is sometimes called the "new school" of orthodontia, and he generally places me among those of the "old school," perhaps not so much on account of my views as of my age. So when I am spoken of as belonging to the old school, I want it to be understood that some of my views are the same as those of the old school, and a great many are in accord with those of the new.

Dr. Summa makes a plea for the use of the word occlusion, and alludes to the fact that I spoke on this subject before this body a year ago. In the selection of terms in dentistry we have the same difficulty that is found in many other branches of the sciences and arts—the difficulty of getting the right word

to express exactly what it is intended to convey. In many cases the word does not exist, and we have either to formulate one or else to be satisfied with one that does not quite cover the ground. To illustrate this, dentists have always had difficulty in describing that portion of the tooth which lies beneath the gum. We have not a word to express it exactly. We once spoke of it as the fang, but the fang is outside, and not underneath the gum; then we spoke of it as the root, and while that is not strictly correct, it is the only word we have to express that idea. And this is so with many other words. For years we spoke of the "nerve" of a tooth, but we now call it the pulp. So also in regard to the matter of occlusion. We have had a number of words—a half-dozen or more—that do not exactly express the idea the term should imply. The word occlusion does not quite express it either, but we must agree upon something. For many years we spoke of it as "articulation" of the teeth, and we have an instrument called the articulator to aid us in arranging artificial teeth, which operation we call "articulating" the teeth. Now in a measure that will do, but articulation means a great many things. For instance, when I speak, I am articulating, and we have articulation of the bones forming a joint. Now, on the other hand, occlusion means to come together; it means the act of placing different things in contact, end to end. It does not relate to the movements of the jaw, but it means coming together, and so while occlusion does not accurately express the idea, it expresses it better than does articulation, and consequently we have agreed to use the word occlusion.

Another illustration. Many years ago dentists were in the habit of speaking of the palatal for the upper, and lingual for the lower inner surfaces of the teeth. This is correct, but we have eliminated one of the words, and we call the upper and lower surfaces lingual because the tongue touches both. We are coming gradually to a better understanding of nomenclature, by the elimination of words that do not serve the purpose or

intention. You know how common it is in everyday life, when we cannot find a word to express a condition or thing, to go to some foreign language for it. And the same thing applies with other languages in relation to our own. For instance the French people have no word for beefsteak, and so they call it "biftek." All do the same thing in regard to other languages.

One other point in Dr. Summa's paper I would like to speak of, and that is in regard to the classification of peculiar conditions. In many cases there is a peculiar abnormal condition of the jaw or in the arrangement of the teeth of an individual, and we notice the same peculiarity in the children of that individual. The essayist says he is not satisfied as to whether this is the result of heredity or environment. It is my opinion that it is not so much due to environment as to heredity, because certain other peculiarities which we see we cannot doubt have been due to heredity. I have in the course of practice seen two individuals each with one brown eye and one blue eye. They had inherited the characteristics of one eye from one parent and those of the other eye from the other parent. That was not environment but was direct transmission, and the same thing applies to other characteristics. But as the essayist also said, whatever the cause of malposed teeth, the duty of the orthodontist is to correct the abnormal condition.

He says a man never has too many teeth. There is no question of that, and in most cases it would be folly to lessen the number. I have taught, as have many others, that wherever it seems to be necessary to reduce the number of teeth, even by one, in the correction of an irregularity—such a course has to be considered in the very rarest cases—this procedure is simply a compromise between a difficult and a simple operation; a question of having a little good done, or not having any good done at all.

Dr. J. A. GORMAN, Asheville, N. C. One of the principal points Dr. Summa brought out in his paper was simplicity, which is the keynote of everything; it

is especially so in orthodontia, both in the matter of nomenclature as well as in that of appliances.

Another point he brought out which is of great importance is the necessity for a study of both arches in the correction of irregularities. How many dentists do you see who come to the conventions with one cast of a mouth in which there exists an irregularity, and want to know how to correct it! What can you tell from one cast? Nothing at all. And yet we have dentists who pretend to straighten teeth by looking at just the cast of one of the arches.

One portion of Dr. Summa's paper appealed to me particularly, namely, the one in which he says that "We must strive to place the teeth in the occlusal relation which is normal for that type of the *genus Homo*." This is something that we should always watch. So many dentists attempt to straighten teeth giving no thought or consideration to that requirement, and without consideration as to future results, frequently leaving the patient in a worse condition than before treatment was begun. Beauty is secondary to perfect occlusion; therefore, non-extraction—by all means! Normal does not mean "natural" as Dr. Guilford said, but typical or regular, and let us all apply occlusion as the basis of all our efforts.

Dr. J. W. PEETE, Memphis, Tenn. Just one point in relation to heredity and environment—one question I would like to ask. If it is not environment instead of heredity that causes these peculiar conditions, why is it that these malformations of family types are in the permanent set only? We rarely see a deformity of the deciduous teeth, and it is perfectly natural that the deciduous teeth should be affected more than the permanent if it is due to heredity. I believe it is more due to environment in every case. Heredity may have a trifling influence, but I believe these malformations mainly due to environment.

Dr. G. V. I. BROWN, Milwaukee, Wis. I was very much interested in the fact that the essayist made the point—the chief one, as I understand it—of bat-

ting for a distinct term that would always represent the same idea. As to whether occlusion is exactly the word or not is a matter of opinion, but I believe it to be the proper term. The fact that we ought to have as nearly as possible a distinct term is beyond question. I am obliged to take issue somewhat with the essayist in regard to his saying that he was not dealing with freaks, and then going on with his paper. Of course, when you are dealing with orthodontia cases you are for the most part dealing with freaks to a greater or less degree.

As to the question of etiology, it seems to me that it should be elaborated upon in this discussion, and particularly in view of the point raised by the last speaker, that generally the deciduous teeth in the mouths of young children are at least to a very considerable degree regular, and he gathers from this fact that the tendency to irregularity increases as the individual grows older, and that it must therefore necessarily be a question purely of environment. Now that does not follow at all, and in order to know why it does not, one should go back to the study of embryonic sections.

Those who have thought of the subject know that this question is decided in a large degree during the very early periods of tooth-life. We know that during the fifth or sixth week the germs of the deciduous teeth are all well under way. The follicle has begun to be formed, and can readily be shown by microscopic sections, and later on there is a budding off from it that becomes the follicle of the permanent set. Anyone can readily understand that even at that early period anything that might disarrange or disturb this cell development will interfere with its normal development. We agree with the essayist that there are certain characteristics which are apparent in these tissues. The tendency to irregular cell development applies not only to the developing teeth, but equally as well to other organs and portions of the body in course of development at that time; and consequently we have come to recognize certain types of dental irregularity

as being characteristic of certain types of people.

Again, taking up the question of environment—this force not only disarranges the occlusion, but interferes with muscular action, and other muscles besides the muscles concerned in occlusion have much to do with the question of irregularity. In speaking of heredity I do not mean to attribute to it that which we recognize as due to environment. I recognize fully that any attempt at correction of this trouble without taking into account correction of these muscular forces will be useless, but I do not like to hear a statement made which places the entire responsibility upon one single factor, for it is apparent that it may rest in any case, according to the individual, upon either or both. As an example I want to speak of greater deformities. I have been keeping a record of cases of hare-lip and cleft palate, and find that the deformity in many instances in a particular family will skip a generation. This happens so often that one cannot question that heredity is a factor. If I once find in the clinical history of that family that there has been paralysis, tubercular tendency, or neurosis, the offspring from such individuals must be people in whom irregular cell development has occurred.

Dr. GEORGE E. HUNT, Indianapolis, Ind. Today, as ever, I approach the ground of the orthodontist with fear and trembling, because I know nothing about it, and I have a high respect for his knowledge of the subject; but rather than speaking of the patients of the orthodontist as freaks, I confess that I am often inclined to apply that term to the operator.

There is, however, one thing I want to speak of, and that is heredity. I was raised on Darwinism to a degree, and I still agree with him. The argument advanced this afternoon in regard to the regularity of the deciduous teeth as disproving the influence of heredity will perhaps lose force if we consider the conditions in the arches when the deciduous teeth are being erupted. These do not fill the arch as do the permanent ones.

As the child grows there is an expansion of the arch, and at the same time the germs of the teeth are assuming their proper position in relation to the position that they will later assume in the matured jaw. It seems to me that the orthodontists ever since they have advanced the theory that because the deciduous teeth are regular, irregularities of the permanent teeth are due to environment, have failed to take into consideration the rapid growth of the jaws and the pressure of the tongue and cheeks in bringing the deciduous teeth into position. We have all seen deciduous canines erupting in an irregular position, but later assuming their proper positions through the growth of the arches and the pressure of the tongue and cheeks. And I believe that we have evidences in other organs as well as in the teeth that these characteristics are due to heredity.

Dr. SUMMA (closing the discussion). I am grateful for the liberal discussion given this brief and somewhat unfinished paper. Its brevity is due to a request of the chairman; and while I also like short papers, I feel that one cannot do justice to a subject in too brief an essay.

Now, in the difficulty of agreeing upon a nomenclature, we resemble the followers of other branches of the sciences and arts. The great biologists have not been able to agree upon a nomenclature for the question of heredity, and if we study this we find that it all comes down to one theme, *i.e.* that there must be transmitted from the parent to the offspring vital units. These vital units have been named differently by different authors. One calls them *gemmules*, another *pangens*, another *biophores*, and still another *micellæ*; yet they are all one and the same thing—vital units. I assure you that the study of this question would also be simplified if biologists could be as harmonious in accepting one term as dentists have been in the acceptance of the term occlusion. I tried to be more explicit in a paper I presented at the last meeting of the American Society of Orthodontists, as regards the question of heredity, the transmission of acquired

characteristics, and the effect of environment upon the position of the teeth. The best that I know at present is that every organ owes its *existence* to a transmitted germ, but it owes its *final form* to that transmitted germ plus the influence of external agencies. During the period of eruption of the deciduous teeth the external influences are less in power, but as the child lives on, it is subject to disease and other influences which impress themselves upon all growth, consequently we find a great tendency to malocclusion in the permanent set.

As to acquired characteristics dealt with in the problem of heredity, we ought first to decide what acquired characteristics are, and then we might, at least in a limited way, decide between transmissible and non-transmissible acquired characteristics; at this time I am only prepared to say that mutilations are non-transmissible. One could argue for hours along this line. There are those who argue that malposed teeth are due to environment, and then again there are those who argue that malposed teeth are due to heredity. I believe that some are due to environment, and others due to heredity, and it will be a problem for the orthodontists to distinguish between these two. We cannot expect to decide this except in a few cases. I believe that the tooth is the initiative for the existence of the calcified jaw, and the development and growth of the teeth mold the jaw under favorable conditions into a normal jaw, but under adverse conditions, into a badly formed jaw. The chief factors concerned in the development of the jaws are the growth of the teeth within them and the external influences, *i.e.* tension of the muscles of the cheeks, lips, and tongue, and the difference of atmospheric pressure from within and from without the oral cavity.

Dr. Guilford spoke of the "old school" orthodontists. There is not so much difference between the old and the "new school" of orthodontists, if we cast aside personal interests. Dr. Guilford and I agreed on more points than many expected. It is a matter of casting aside personal feeling to work out fundamental

principles, and the slight difference of appliances can be readily remedied.

In closing I wish to thank both the society and the discussers for their kind attitude.

The next order of business as announced by the President was the reading of a paper by Dr. GEORGE H. WILSON, Cleveland, Ohio, on "Phases of Art in Prosthesis," as follows:

PHASES OF ART IN PROSTHESIS.

Twenty years ago there was much discussion about dentistry being a specialty of medicine; today we are more concerned about the specialties of dentistry. There are several distinct departments of the science and art of dentistry that are being more or less specialized. The more prominent ones are operative, prosthetic, orthodontic, prophylactic, surgical, and mechanical. There is no well-defined natural line of demarkation between these specialties—each overlaps the other; however, arbitrary lines are being drawn. It is only necessary in this paper to define what we understand as the province of the department of prosthesis. Therefore we define prosthesis as the science, art, and esthetics of restoring a lost dental organ or organs and their associate parts with an artificial substitute. Science is the classified knowledge pertaining to the specialty; art is the skillful doing of the work; and esthetics is the harmonizing of the instrument with its environments.

This definition states, as the minimum field, a lost dental organ. Here is where an arbitrary line dividing the two departments, operative and prosthetic, is necessary. The prosthetist considers when so much of the natural tooth is lost as to necessitate the substitution of an artificial crown that the case belongs to his department; while the operator could justly claim the case so long as a restoration can be attached to the root. By the definition, a bridge undoubtedly belongs to the prosthetist, but a bridge cannot be attached without a crown, some modification of a crown, or some form of attach-

ment that belongs to operative dentistry. Hence it is apparent that the line must be drawn with the crown of the tooth, giving the case to the prosthetist as soon as a full artificial crown is required. The setting of an artificial ready-made crown does not logically belong to prosthesis, and ought not to be considered as belonging to the operator. If the entire profession were divided into the two specialties—operative and prosthetic—and the line of demarkation as laid down were rigidly adhered to, there is no question but that more natural crowns of the teeth would be saved than if artificial crowns of some or all forms were considered as operative work. The treating and preparing of roots and teeth for crowns and bridges is really operative work, but it will usually be for the best interests of both patient and dentist if the prosthetist prepares the abutments for the superstructure he is to build. Assuming that the minimum field of the prosthetist is the construction of a crown, and that he may be required to supply appliances for lost lips, noses, cleft palates, excised mandibles and maxillæ, and fractured jaws, his usual field of service consists in restoring masticating surfaces and the contour and harmony of the lower third of the face.

Society recognizes two kinds of art—utilitarian and esthetic. Someone has said that the difficulties of prosthetic restoration increase with the amount of lost tissue to be restored. As time is limited, we will consider in this paper only the restorations for well-resorbed edentulous jaws. We desire to discuss certain phases, both utilitarian and esthetic, of restoration, without discussing materials.

When the teeth are extracted certain physiological changes take place, which are usually quite complete in from one to two years. These changes consist of a resorption of a large portion of the alveolar processes and their integuments. Nature has designed, although in ninety-five per cent. of cases the upper teeth overlap the lower, that the dental curve of the lower teeth to be greater than that of the upper, and the long axis of the teeth a slight incline, with the end at the

apices of the lower teeth farthest from the center. It naturally follows that the relative positions of the curve of the summits of the alveoli are much changed as resorption takes place. As the alveoli of the maxilla recede upward and inward, the summit curve must diminish; and as the alveoli of the mandible recede downward and outward, the summit curve must expand; hence the anatomical relation of the summit curves has been entirely destroyed, and it has thus added greatly to the difficulties of a utilitarian restoration of the lost organs. Besides the changed relation of the fulcrum for the restorative appliance, the features have been distorted by the settling of the origin of five pairs of muscles of expression.

The depressor *alæ nasi* and compressor *nasi* both arise in the upper incisive fossa, and are inserted respectively into the septum and wing of the nose. By the process of resorption, either these muscles are stretched or the tip and wing of the nose are depressed. It is obvious that any attempt at padding out these muscles with an artificial appliance will only exaggerate the deformity.

The levator *anguli oris* arises in the upper cuspid fossa, and is inserted in the angle of the mouth. The resorption of the process does not put this muscle upon a strain, yet it is necessary in the artificial denture to notch out its periphery and buccal surface, just back of the cuspid eminence, or the muscle will be very much distorted and the patient will have the appearance suggestive of a constant snarl.

The levator *menti* arises from the lower incisive fossa, and protrudes or rolls the lip outward; thus when resorption has taken place, and a restorative appliance is inserted, no strain should be placed upon this muscle.

The depressor *alæ nasi*, compressor *nasi*, and levator *menti* explain why the periphery of the upper and lower dentures must slant from the cuspid eminences to the median line.

The buccinator arises from the buccal surface of the alveolar process of the maxilla, and is inserted in the buccal sur-

face of the alveolar process of the mandible. As both the origin and insertion of this muscle have receded, it is apparent that a restoration to the original contour of the tissue is impossible. Also it must be remembered that this muscle is not only a muscle of expression, but of mastication, and that too great an attempt at restoration will interfere with the retention of the denture.

When we consider that an upper denture is held in position by adhesion through contact, and possibly temporarily by atmospheric pressure—and in addition to this, the exaggerated relation of the summit curves, also the action of the buccinator muscles—then it can be easily comprehended why the physical laws of leverage are such an important factor in dental restoration.

If these statements are facts, then it is a logical deduction that it is a physical impossibility to make a perfect anatomical restoration. It is also a justifiable conclusion that the insertion of an artificial denture is no mean or trivial operation; that it requires the knowledge of a scientist, the skill of an artificer, and the judgment of an experienced esthetist.

Does it seem an imposition upon a trusting public for a careless operator who despises "plate work," with the aid of a mechanical laboratory to insert artificial dentures? Undoubtedly the patient will be better served because of the mechanical laboratory, even though it be a thousand miles away, than if the indifferent operator had made the "job." It is true there are operators with the esthetic sense so well developed that, with the aid of a mechanical man, they will better serve the patient than the average prosthetist, and possibly better than any prosthetic specialist. If this should be the case, it is because of the different caliber of the operator and the specialist. No argument is necessary to prove the assertion that any man, no matter how brilliant, will nearer reach perfection by confining his talents to a narrow line of work than by dividing his time and energies between several specialties that are only indirectly associated. It does not follow because a man is devoting his entire

time to a special line of work, that he is enriching the field of that specialty, for there are comparatively few minds capable of originating and executing new ideas. Some one has said, "One truth discovered is immortal, and entitles its author to be so; for like a new substance in nature, it cannot be destroyed." Most of us follow, and do well to perfect ourselves in that effort. However, it is reasonable to suppose that any man will do better work if he confines himself to a limited field than if he tries to do many things.

Recognizing the changes that have taken place in both the hard and soft tissues, two things are required of the prosthetist: to restore the ability to masticate—and to beautify. The first of these is not within the province of this paper; and we regret our limitations in dealing with the other. However, we make our offering, trusting it may help some, and prompt others to carry the subject to its fruition.

Before we proceed we must define the two words, "normal" and "natural." Last year in his paper on "The Nomenclature of Orthodontia" (DENTAL COSMOS, vol. xlviii, p. 135) Dr. Guilford stated: "*Normal* does not mean natural, as one would often infer from its common use. Its definition is 'conforming to a type or standard.' Its synonyms are 'regular' and 'typical.'" *Natural* is pertaining to nature, as produced by nature. Thus we say the alignment of the teeth and profile of the face are natural, because they are as produced by nature; but they may or may not be normal. If they do not come to the line of harmony, they are not normal. If there is perfect harmony, then there is perfect beauty of form, dependent upon the beauty of the type.

We assume that the Creator designed that every soul should inhabit a perfect body. According to its type it should be like the Greek creation Apollo, every line and every inch godlike in its perfection. Had the original design prevailed, there could have been no beauty associated with the human form, because there would have been but one type, and each individual would have been a duplicate of all

others. Beauty is appreciated by contrast only. The Creator also gave the laws of environment. Therefore we have no two persons that are exact duplicates of each other. As the body is molded and shaped by external mental and physical influences through conception and gestation, and by both external and internal mental and physical influences through infancy, youth, adult, and senility, there can be no perfect duplicate or absolute conformity to a given standard; and yet how wonderfully alike are human beings!

Ethnologists, physiognomists, and other scientists have divided and subdivided the human family into many classes for the purpose of better studying man. So far as prosthetists are concerned, our studies have been confined almost entirely to the Caucasian race, and we consider only such classification as will aid us in understanding the needs of our profession. We first divide the race into two classes—light (blond) and dark (brunette)—a simple classification easily understood and which calls attention to certain facts. The next classification is into "temperaments," dividing the race into four or five classes, according to the classification chosen. These divisions with their various combinations will carry us much farther into the physiological study of our patients; will establish types, and teach us to note the variations in each subject from the type.

Another classification we may call the "dental profile" classification. Scientists consider this subject as a study of the facial angle, and make two general divisions—orthognathous and prognathous. This division is of little value to the dentist, yet the study of the profile is perhaps the most important of all the classifications for the prosthetists.

For convenience of study we divide the dental profile into three classes—*straight* profile, *convex* profile, and *concave* profile.

Scientists, in drawing the perpendicular line of the face, have it touch the most prominent point in the median line of the forehead and the most advanced portion of the maxillæ.

The dental profile line is somewhat different from the perpendicular facial angle line.

The first class, or straight profile, is the ideal Greek face. The perpendicular line has three points of contact—the frontal and mental eminences, and the middle of the wing of the nose. The lower lip will just touch the perpendicular line, and the upper lip will be a little in advance of the line. There is no question that this is the normal profile of the highest ideal of beauty.

The second class, or convex profile, has two points of contact with the perpendicular line—the frontal eminence and a point at the base of the nose that is the same distance from the middle of the back of the ear as the frontal eminence. In the type this point will be the center of the wing of the nose.

The ideal standard of this class has the face made up of rounded, graceful curves; forehead high and slightly receding; nose Greek or Roman type; lips full but not coarse; chin receding but not weak; teeth, both number and alignment normal. No competent orthodontist would think of converting this ideal of our second class into the first or straight class, for he would recognize that the harmony of the features would be destroyed.

The third class, or concave profile, has the frontal and mental eminences in contact with the perpendicular line. It is not possible to conceive of this profile being a mark of beauty, and it is fortunate that the class is small compared with the other two. It is a condition confronting the prosthetist, and he must place the features in as pleasing a relation to the concave curved line of the individual as possible.

The physiognomy of man is gradually changing and tending toward new types. The intermarriage of different nationalities and the modes of living, causing mental development and physical degeneracy, partly account for this condition. For the last few years the orthodontists have been impressing upon our attention the importance of teeth in the physiognomy of man, and giving us a rational

reason for many of the abnormal conditions. This same study is of value to the prosthetist, as it aids him to understand the designs of nature for the individual case, and aids him also in classification. In studying the harmonies and inharmonies of the face, it is important that we consider the causes as well as the effects.

These few thoughts upon the profile have been given to impress the importance of the subject, and to show that it is a rich field for original work.

When the prosthetist has studied the individual case and classified it, he is confronted with the question: What is one's duty, to restore the features to the natural or to the normal condition? It is apparent that a normal convex profile should not, in a portion of its outline, be converted into the concave type, and thus form an ogee monstrosity. Each individual case must be kept within its normal class, and then it is a matter of judgment for the prosthetist and patient to decide how much the natural peculiarities shall be modified.

It should be borne in mind that physiognomists make a distinction between the anatomy and the expression. Expression is of the soul, by or through the anatomy. Therefore deformities of the anatomy may belie the soul. The prosthetist should study well to have the teeth of the proper size, color, form, and arrangement to harmonize with the rest of the anatomy of the face. The esthetics of prosthesis may be expressed thus—"anatomical harmony" and "pleasing in expression."

The next phase we shall consider is the prosthetist himself. For information upon the subject we sent a letter containing the following questions to seventy-one college teachers, and later to eight men referred to us as specialists:

Are you teaching Prosthesis? What school? Do you practice prosthesis as a specialty? Do you operate, or do any other line of dental work? Do you do laboratory work for other dentists? Do other dentists send their patients to you for prosthetic work?

Please give me the name and residence city of all dentists whom you know to be con-

fining themselves to prosthesis as a specialty. I do not want parlor men, or commercial laboratory men who work for dentists only. I do not desire the name of any man unless he is a legal practitioner, and works at least part of the time for patients.

From the replies received we give the following summary: The number of men devoting their entire time to the prosthetic specialty is 11. Of these 4 are teaching prosthesis but not conducting a practice; and 1 is devoting his entire time to crown and bridge work and teaching. All others, though much interested in prosthesis, are conducting a general practice.

Who should take up the specialty of prosthesis? Those men who have been a few years in general practice, and have acquired a love for and a reputation in this line of work. No man is justified in giving up his general practice unless he is certain his dental *confrères* will support his efforts by referring their patients to him. The prosthetist must bear in mind that it will be the case—as it should be—that the patients, as a rule, will first go to an operator.

It is the opinion of the essayist that it is impossible to build a living practice as a prosthetist without the assistance of the operators.

The field is great, and there is room for a large number of skilful prosthetists if the dentists will support the latter rather than the cheap laboratories. With a body of men devoting their lives to the science, art, and esthetics of this specialty, we could expect great advancement within a few years.

Discussion.

Dr. C. J. GRIEVES, Baltimore, Md. I received Dr. Wilson's paper some time ago, and having studied it carefully, I must say that I am much impressed with his effort to give us definite mathematical lines by which we could produce art. I do not say that this is possible, but I do say we should try along those lines, and should thank Dr. Wilson for his efforts. I cannot agree with him in the contention that dentistry should be further di-

vided into specialties. Orthodontia lends itself very completely, in my estimation, to assignment as a specialty, and for reasons we all know. Dr. Wilson has defined the prosthetist as a man who does everything in dentistry except the filling of teeth, the simple treatment of the soft tissues when such treatment is necessary, and that of the pulp-canal with its contents for the preservation of a tooth. All else, he says, is prosthesis, and operative dentistry is to be confined to some such limited field. Later on he tells us that the patient would naturally go first to the operator. I thoroughly agree with him, and believe it would be a great misfortune to divorce the laboratory—the old-fashioned laboratory—from the dental office. Historically we came near abandoning it at one time, when, on the introduction of vulcanite, the operator looked down upon the man who did rubber work, and the mechanic despised the man who would not soil his hands. Then came crown and bridge work into the breach, as, in my estimation, the greatest savior of scientific mechanical dentistry, bringing the laboratory nearer to the operating room, where it justly deserves to be.

So much of what Dr. Wilson calls prosthesis—beginning with the treatment of the root and the placing of the artificial crown, clear on through bridge work, dentures, vels, splints, and what not—is really operative dentistry, that it has for a long time been my belief that instead of separating prosthesis from the operative chair, prosthesis should be brought to the chair—that is, more operative methods should be applied to the production of prosthetic appliances. I should consider it a great misfortune if dentistry were to be further subdivided, thus widening the chasm between prosthesis and operative dentistry. It is largely a matter of juggling with terms. The simple question is, whether the public will be better served, and the dentist made happier by such a subdivision, or whether both will not save time and be more contented if this work be done by one man; that is the point to be consid-

ered. For instance no two men could possibly reach the same conclusion as to the exact time when the mouth is fit for the placing of a denture. On the contrary, if one man carries out all of the different steps in the operation, he may follow different methods from those of the specialist, but to my mind he will get just as good results. In the matter of excluding occlusion from the field of art in prosthesis, I think the essayist is decidedly paradoxical. No matter what the art may be made to embrace, it would not be possible to exclude occlusion from the process of making a denture.

Dr. Wilson has defined the muscles of expression, and has described their insertions. It is a rule in anatomy that if a muscle has one insertion it has another. These muscles have another insertion, and that is found in the orbicularis, and the orbicularis being a sphincter may be said to have a movable insertion in its contact with the teeth and the alveolus. Therefore, when the teeth are lost, contraction of all this mass of muscles including the orbicularis will follow; coupled with such contraction a shrinkage of the alveolus will take place. The alveolus is a transitory structure which, particularly after certain diseases, as pyorrhea, goes on wasting definitely. Thus we may have in mind for some such case Dr. Wilson's ideal convex facial line, and have to be satisfied with a concave profile eventually. All we can do is to produce utility combined with art. It would be the highest ideal, if we could bring our practice up to the standard set by Dr. Wilson, and I hope we may. If we can but learn and teach the art of prosthesis so that every man practicing it (and most of the gentlemen whom I see before me are practicing it), particularly those in the country and in the smaller towns, where it would be impossible to have prosthetic specialists, may do the best that is possible, esthetically, under the circumstances, after giving the occlusal lines and the arch and ridge due consideration, I think it is all that is needed and is that which we should be doing now.

Dr. C. L. ALEXANDER, Charlotte, N. C. With regard to that portion of the paper in which the essayist refers to the line of demarkation between the prosthetic and the operative dentist, I think it would be very difficult to get both branches into closer relationship than he has described. While I do not agree with the essayist at all as to the matter of specializing, I wish every man practicing prosthesis could read his paper. If we had a better knowledge of the oral cavity and its associate parts before and after resorption, I am sure it would enable us to do more artistic and useful work, and to arrive nearer the ideal which every man must have in his mind as to how work should be done.

I am sorry Dr. Wilson did not describe some of his methods of arriving at results, because it would have helped us more than anything else. Theory is all right in its place, but without practical results it is a failure.

I will endeavor to describe one method that I have adopted in the making of artificial structures—say a full denture. After preparing the cast, I produce in modeling compound forms of such a shape as to represent the plate, teeth and all, just as we want them to appear in the mouth. By doing this, and putting the forms to place in the mouth, we can see where restoration is necessary, being careful to trim the forms to allow for all lingual and muscular movements. In this way we obtain casts which may serve as guides in the construction of the permanent dentures. Those of you who have not tried this method will find it a great help in arriving at satisfactory results.

Dr. B. J. CIGRAND, Chicago, Ill. I am very much interested in this paper. It covers so much ground that I am at a loss to know where to begin or where to leave off. Dr. Wilson has gone over so much matter that I feel that I must congratulate him for the labor involved in the preparation of the paper. Anyone who attempts to give us anything new in what appears to us a foreign territory must, of necessity, give much of his time and considerable attention to the subject.

I am rather inclined to think that the essayist is going too far when he advocates so much specialization in dentistry. I do not believe in the subdivision of dentistry into too many specialties, viz, porcelain work, operative work, prosthetic work, and what is advocated by some—the subdivision of prosthetic work. I think we are subdividing too much, and I believe in this subdivision there is loss, because we lose the spirit of the general, and when we lose that we lose much of the substructure. I think the profession is sufficiently subdivided now for us to keep in touch with everything that we love. My profession is dear to me, and I do not like to hear of its subdivision if it can be avoided. I like operative work, porcelain work, and crown and bridge work, and I do not believe it is a good idea to advocate the subdivision of a subdivision; not that I think that what we say here today will be done tomorrow, but it may be done sometime. There is sufficient work for us to do in other lines, and if we can perfect the nomenclature of our profession, we will be building a straight line to a given point. There are too many words that mean the same thing. I would like to see our nomenclature simplified, so that when a statement is made, its real significance will be understood.

That dentistry is thoroughly and absolutely wedded to art is an emphatic truth; art in every phase of the word—in color, shape, shade, and build. There is in every phase of art something that appeals to us as dentists. When we walk out on the streets of this beautiful city of Atlanta, and see the great architectural structures, there is something which appeals to the dentist. When we go out into the realms of the railroads and see the immense bridges that span the streams, we find something there that appeals to us artistically. Everything in art is more or less part and parcel of what we as dentists are working for. We should not relegate too much to specialization, but keep close to the general practice, as it broadens the mind and certainly educates the hands. We should

identify ourselves with other associations, meet in other conventions, and subscribe to other journals, in order to keep in touch with those who are laboring for the same thing as are we—to make more beautiful and preserve that which God has given us.

This subject is broad, and so far-reaching that I will not attempt to go into it farther than to say that I am glad to have been called upon to discuss this excellent paper, since it is in thorough keeping with the art impulses of our calling.

Dr. WILSON (closing the discussion). I was very glad to hear the differences of opinion expressed, because that is the means by which we learn. If all agreed with me, then I should feel that I had not made any impression upon you.

Dr. Grieves somewhat misunderstands my position in regard to specialties. I do not for a moment advise any man to take up a specialty until it is taught in the colleges. When a man becomes interested in a particular line of work more than in any other, there is no question that if he confines himself to that line of work exclusively he will progress faster than before. It is also true that specialists are liable to become narrow in their views. Our whole profession narrows a man, and when it comes to a smaller part of the profession, it tends to make a man still more narrow. The question arises here as to whether we are working for the profession, or whether we are working for our selfish selves. If we intend to work more for self than for the development of the profession to which we belong, we should never go into

any profession, because we will not do it any good; but if we are working for our profession and will specialize, we will probably do more for it than otherwise, provided we have the qualifications for that profession.

Consequently I say that Dr. Grieves misunderstood the meaning of my statement on specialties in the profession, and when he claims that I would have the prosthetist take in all of dentistry except a minor part of the operative man's work—that is, preparing cavities, inserting fillings, etc.—he likewise misunderstood my statements. There is a great deal more in the operative field than those operations. We have materia medica and therapeutics, and these subjects should be a great field for the operator. Of course he must put in fillings, as a part of the treatment, but there is a great deal in the therapeutics and pathology of dentistry. I would not for a moment have the prosthetist trespass in the field of the operator. His business is to take the mouth after the dental organs are lost, and not to attend to the operative phases of the work, because he is not prepared for it. And likewise the man who practices operative work and restores the teeth to their original usefulness should not enter the field of the prosthetist, because he is not prepared to undertake this phase of dentistry. I believe that as a profession we can advance still more by having certain men take up certain lines and follow them out. And I hope that the ideas I have advanced along this line will receive consideration and will do some good.

(To be continued.)

NEW YORK ODONTOLOGICAL SOCIETY.

Monthly Meeting, November 1906.

A REGULAR meeting of the New York Odontological Society was held on Tuesday evening, November 20, 1906, at the Academy of Medicine, No. 17 West Forty-third street, New York city. The president, Dr. Van Woert, occupied the chair and called the meeting to order.

The special paper of the evening was read by Dr. FREDERICK C. KEMPLE, his subject being, "Orthodontia as a Prophylactic Measure."

[This paper is printed in full at page 337 of the present issue of the COSMOS.]

Discussion.

Dr. M. L. RHEIN. I had the pleasure of reading a copy of the essayist's paper some days ago, and have had some little opportunity for studying it, and I believe this society is very much to be congratulated in having this paper presented to it. It is barely possible that in the reading of an essay of this kind, or in listening to it for the first time, its full significance may be somewhat lost—not that anything startlingly new has been presented by the essayist, as the facts that we have listened to ought to be familiar to all of us—they seem to be incontrovertible—but the one fact remains that prior to this occasion the subject has never to my knowledge been publicly presented to the profession. The importance of prophylactic treatment of the mouth has been made very emphatic for a great many years past, and, to speak broadly, the disciples of prophylaxis of the mouth have been unquestionably growing in number year by year.

Now, what has the essayist presented to us in regard to this fact? We are pretty generally agreed on what he has laid down, viz, that if you keep the mouth in an absolutely clean condition,

you will keep that mouth in a physiological condition; you will keep it free not only from the invasion of caries, but also free from other diseases that attack the dental organs sooner or later and with more or less emphasis. This question of keeping the mouth clean seems very easy at first sight, especially to the layman when it is presented to him, but we know what a difficult matter it really is. In my attention to this subject, I have become acquainted with the fact that dentists have very different views as to what a clean mouth is. To say that it is kept in a sterile, hygienic state admits of very different ideas, according to the dentist who makes the statement. It has been a not infrequent matter to have patients look with astonishment at me when I have said to them, "The first thing that is necessary in your case is to keep your mouth in a sterile condition—clean absolutely," and to have them inform me that it had been but a short time since the mouth was cleaned, and they do not think they ever had it in a cleaner condition.

The point that I wish to emphasize in conjunction with this fact is the following: It is scarcely possible to keep a mouth clean many days or many hours without operative interference on the part of the dentist. In other words, accretions that first deposit themselves upon the enamel surface are microscopic in character. They are of such a nature that they are imperceptible to the eye. This has been very beautifully illustrated by some of Professor Miller's latest work. Now, when these accretions have increased in thickness to a very considerable extent, they become unrecognizable to a great many dentists because of their similarity in color to the tooth-substance, bathed as they are in the oral fluids. It

is not uncommon for me when I am instructing a student in the method of mouth-cleansing, to show him a large amount of accretion left upon the tooth-surface that he has absolutely failed to perceive. The adjustment of the rubber dam to such a tooth and drying of the surface is frequently sufficient to open the eyes of the student to the fact that he has not been able to distinguish this accretion on the enamel surface.

The essay of the evening is replete with merit, and I have looked through it from beginning to end with the deliberate object of endeavoring to find some point of attack upon the essayist, and from my standpoint it is invulnerable in this direction. It is not my object to discuss methods of prophylaxis, nor prophylaxis in its advantages to the preservation of teeth. I am taking it for granted that this is an admitted fact, and I believe it is so by the majority of the profession at the present day, although I do occasionally see some patients who look aghast when I suggest a treatment of this kind every four weeks, or sometimes every three weeks. They remark that the last dentist always told them that such a course would invariably result in the ultimate destruction of the enamel. I think the number of men in the profession today who make those statements is constantly becoming smaller and smaller, so I do not propose to go into the merits or demerits of prophylaxis; but the point is that if every mouth were a normal physiological mouth, or as nearly such as possible, dental prophylaxis as it is understood would become a very simple matter, and operative dentistry would likewise become a comparatively easy thing for all of us.

But we find mouths in which there is more or less malocclusion, where the alignment is wrong and other irregularities of the arch exist that harass the life of the operator, and where additional operations have to be done, and as a result each operation becomes in turn almost an individual invention. This applies as much to operative dentistry as it does to the dentist who is attempting to practice prophylactic dentistry, be-

cause it makes it necessary for such a mouth to be treated much more frequently than if it were in a normal, physiological state, for the reason which the essayist has demonstrated—the difficulty the patient himself finds in keeping such a mouth clean.

I want to indorse very strongly the criticism which the essayist made in regard to a statement of Dr. D. D. Smith's, that in this age of civilization mastication and the use of the normal teeth were unnecessary for the maintenance of life in its normal form. Since this remarkable statement of Dr. Smith's—I believe it was in 1902 or 1903 at Washington—I have looked in vain to find one man, either in medicine or dentistry, who has lent his support to such a peculiar and astonishing statement, and I am very glad that the essayist has taken up this matter and condemned it in such strong terms. I want to add my quota of adherence to what he has said as to the theory that the entire head is benefited from the use of the jaws in mastication, and in order that they should functionate properly, it is important that the teeth should not be in an irregular position. The experiments that he has noted, conducted by Professor Fisher in elaborating what is known as the "Fletcher idea" are certainly most corroborative of this doctrine, and, drawing aside a moment from the purport of the paper, I will say that every dentist in the world should do his utmost in educating the mothers of the community in the value of complete mastication and insalivation of every particle of food that is taken into the mouth.

This has been a matter upon which I have felt strongly from the first day I entered the practice of dentistry. There is nothing new in it; the teachings of physiology thirty years ago were as strong and clear and patent on this point as they are today, and nothing has been discovered in all this time that has changed our views on this subject. I presented the essayist with a few slides of my own for him to show in corroboration of some of the points he has made, but he very modestly preferred that I show them myself. The point I want to

illustrate first is this: The last slide that the essayist showed us of a normal physiological articulation and occlusion is an object lesson on this point.

If you read carefully the essayist's paper, you will see that he does not speak of irregular teeth producing pyorrhea, but he speaks of the condition as having a strong influence in that direction. Everybody that has studied the conditions of pyorrhea realizes that any form of irregularity at all is a strong contributory force toward pyorrhea. Wherever there is malocclusion, lack of articulation, improper spacing, or crowded arches—those are the points which if found in a case of malnutrition indicate that pyorrhea is going to be most marked, and frequently they are found where pyorrhea is apparent for the first time.

[Dr. Rhein then exhibited by means of the projecting lantern a number of slides of cases bearing on the subject under discussion.]

There is today as strong an objection to a radical handling of irregularities of the teeth at a young age, as there was a number of years ago to the question of the value of prophylaxis, and the point that has been brought out so far this evening is to demonstrate what a boon it will be to future humanity if the dentist will use his utmost endeavors with the parents of the children—when there is a question of some form of irregularity—to have their mouths put in a normal physiological state at as early an age as possible. The public, however, is not altogether ready for this. I have seen this duty very plainly for a great many years, and in trying to follow it I have lost more patients than from anything else that has occurred in my practice. When I say I have lost patients, I mean that when I have pointed out to the parent that it was absolutely necessary that the child's teeth should be regulated for the welfare of the future of that child, I have again and again lost the family as patients, because I refused to attend to the child unless this was done. Generally they consulted other dentists, and would then come back and say, "I have gone to Dr. So-and-so, and he said that

if that were his daughter, he would leave it to nature." I have simply said to those parents, "I disagree with Dr. So-and-so, and you must make up your mind whose advice you are going to follow, because if you are not going to follow mine, you cannot remain my patients." It is for that reason that I made the statement that I had never seen the thing presented as the essayist has presented it tonight, and in my opinion he has expressed it absolutely correctly, and I do not see how any legitimate criticism of his standpoint can be taken.

President VAN WOERT. We have with us a gentleman who, while he is not a member of the society, has come among us in Brooklyn, and makes a specialty of this subject. We should be glad to hear from Dr. Gough.

Dr. GOUGH. I consider the important point, as has already been brought out by Dr. Rhein, is the strong argument in favor of early interference in cases of malocclusion, and there are plenty of other reasons why there should be interference and treatment at an early age. This, it seems to me, is only one of them, but its importance has not heretofore been sufficiently emphasized.

Dr. HILLYER. I would like to set myself right. As I understand it, any dental practitioner takes first the precaution to see that the teeth are in perfect order. Do I understand that an orthodontist eliminates that entirely from his practice? If a patient consults such a specialist does he place that patient in other hands to be put in absolutely hygienic condition, or is it his practice, as I have always understood it was, to see personally that the mouth is put in proper condition before the operation?

Dr. KEMPLE (closing the discussion). Dr. Hillyer inquired concerning the prophylactic care that the teeth receive during treatment. If a patient whose mouth was much in need of thorough prophylactic care should apply to the orthodontist for treatment, the orthodontist would probably refer the patient to the dentist to have the mouth put in as sanitary a condition as possible before placing appliances on the teeth. During treatment

a constant watch would be kept on the teeth to see that they did not suffer through lack of cleanliness; the patient would be urged to keep the teeth carefully but thoroughly brushed, and at each visit any necessary cleansing would be done. Before placing a band on a tooth every surface of the tooth should be polished with pumice, then thoroughly dried and a thin cement coated over the

tooth as well as being placed inside the band. Observing these precautions there is little possibility of the teeth receiving injury from the appliances used.

Dr. GOULD moved a hearty vote of thanks to Dr. Kempe for presenting this subject, which was carried.

Adjournment.

WM. B. DUNNING, D.D.S.,
Editor N. Y. Odont. Soc.

FIRST DISTRICT DENTAL SOCIETY, STATE OF NEW YORK.

Monthly Meeting, February 1906.

THE First District Dental Society of the State of New York held a regular monthly meeting, Tuesday evening, February 13, 1906, at the Academy of Medicine, No. 17 West Forty-third street, the president, Dr. Arthur L. Swift, in the chair.

INCIDENTS OF OFFICE PRACTICE.

The PRESIDENT. Dr. John H. Meyer has two cases which he wishes to bring before us. We will be glad to hear from him at this time.

Dr. Meyer read the report of a case of fracture of the maxilla which he had treated, as follows:

John H. Reilly, clerk, twenty-seven years of age, was admitted to the New York Hospital October 9, 1905, suffering from a compound fracture of the mandible, the point of fracture being approximately between the left side of the first and second molars. Two bicusps and two molars were missing on one side of the fracture, and one bicuspid and two molars on the opposite side. There were no occluding teeth in the maxilla on either side. An external abscess had developed, and the swelling of the face was so great as to close the left eye. The temperature was 104°. An opening was made under the site of the fracture to allow escape of pus, and the wound was dressed daily. The patient left the hospital October 13th, and became a patient of Dr. C. On Novem-

ber 21st he became a patient of Dr. G., who operated and removed the first molar and a piece of bone one and one-quarter inches in length, and wired the jaws together. The wire in a few days slipped through the process and tissues, both upper and lower, causing severe laceration of the gums and necrosis of the alveolar process.

On December 11, 1905, sixty-three days later, I took an impression of the maxilla and mandible with modeling compound, for the purpose of making an interdental splint. The mandible was greatly swollen and much contracted toward the point of fracture. A running abscess was also present. Impressions were obtained with great difficulty. The casts were made in the ordinary way, and there being no occluding teeth, they were placed in the articulator, using the median line as a guide. The splint was constructed in one piece, covering the anterior upper and lower teeth. On December 12th the splint was inserted and held in place by being tied to the upper bicuspid and to the lower first molar and canine. On December 15th the bandage was removed, and the discharge of pus had ceased. A piece of necrosed bone, half the size of a ten-cent piece, was also removed. On December 22d the splint was removed, and a large opening was made between the four canines, exposing half the length of the lower incisors. This gave the patient more freedom of speech. Nourishment was taken through a tube, and also through the spout of a tea-kettle, behind the splint on the left side. The case is progressing nicely. I would take this opportunity to condemn the wiring of the jaws in fracture

cases when an interdental splint can be obtained for the asking, either at the New York College of Dentistry or the New York College of Dental and Oral Surgery.

Several weeks ago I discovered that the fracture was between the second and third molars. It has also developed since then that the upper right first and second molars and the lower left second and third molars articulated. The swelling was so great that the mouth could not be opened. Inasmuch as it would take too much time for all to see the case, I would request Dr. Sanger, Dr. Littig, and Dr. Deane to examine it, and give their opinions to the members present.

These gentlemen then examined the case as requested.

Dr. W. C. DEANE. I would like to report that it is a pleasure to see a patient in a case of this kind presented before professional men with such a clean mouth. I also wish to compliment Dr. Meyer on the results accomplished.

Dr. J. BOND LITTIG. I think the results are really more than might have been expected, in view of the circumstances and the time that elapsed before that fracture was treated properly.

Dr. R. M. SANGER. I can only reiterate what the other gentlemen have said.

Dr. MEYER. From the report of the examiners and the general appearance of the occlusion of the teeth, one would naturally infer that the fractured bones were in, or nearly in, their original position, but the X-ray picture taken two days ago tells a different story. While the forward part of the mandible is in position, yet the condyle has been drawn upward about one-half inch. This part, however, will slough off when thorough union has taken place.

Dr. DEANE. Might I ask why Dr. Meyer still continues to have the patient wear the splint?

Dr. MEYER. The union is not strong enough to warrant the removal of the splint.

Dr. DEANE. Why would not the use of a chin-piece and a head-bandage be indicated to draw the mandible inward?

Dr. MEYER. I am glad you spoke of that. The mouth having been open for over two months, naturally the muscles have stretched, and I have no doubt that after the splint has been removed the muscles will contract and bring the bite closer; but should they not contract sufficiently, I will grind off the teeth on the right side and bring them to a closer occlusion. But even if the occlusion is not perfect, the patient should be thankful for the result already attained.

Dr. Meyer then showed a plate he had made for a case where there was a large perforation of the palate. (See DENTAL COSMOS, 1906, vol. xlviii, p. 916.)

Dr. MEYER. I have the case in my pocket. The gentleman kindly sent it to me from Florida, with a letter saying, "For God's sake, doctor, don't let anything happen to this." I therefore have it in one pocket, and a dummy in the other. I will pass around the dummy and you can see the original if you wish after the meeting.

Dr. Meyer then read a description of the plate.

The paper of the evening entitled, "The Law and Ethics of Dentistry," was then read by Dr. F. W. PROSEUS of Rochester, N. Y.

Adjournment.

B. C. NASH, *Secretary*.

Monthly Meeting, March 1906.

THE First District Dental Society of the State of New York held a regular monthly meeting Tuesday evening, March 13, 1906, at the Academy of Medi-

cine, No. 17 West Forty-third street, the president, Dr. Arthur L. Swift, in the chair.

Dr. P. FIASCHI of New York pre-

sented two interesting cases, which the society were privileged to examine.

[Dr. Fiaschi's report of these cases was printed in full with illustrations in the DENTAL COSMOS for March, page 262, entitled "Report of a Case of Extensive Injury to the Bones of the Face, and of a Case of Post-Typhoid Osteomyelitis of the Mandible."]

The subject of the evening was then taken up. It consisted of an address by Dr. S. G. PERRY, New York city, entitled

A DISCUSSION OF THE MERITS AND DEMERITS OF THE GOLD INLAY.

In looking over the history of dentistry, it seems to me that in Dr. Atkinson's office there arose an ideal of dental operations that was perhaps as high as any that we have ever had. It is no injustice to those who are dead, or to those who are living and who had their first inspiration from that office in those early days, to say that no higher mark has ever been reached—before or since—than was worked out in Dr. Atkinson's office. You naturally think first of Dr. Varney, who had his inspiration in that office, Dr. Charles Butler of Cleveland, Dr. Delos Palmer and Dr. Eugene Palmer, co-workers with Dr. Varney, although at that time young men. I think it is a very safe thing to say that we have never reached a higher point in the art of filling teeth with gold than was reached by graduates from that office, even to the present time. I do not believe it is possible for human hands to ever do better work than was done by, we will say, Dr. Varney and later by Dr. Webb—of cutting very freely into the sound structure so as to avoid recurrence of caries underneath; so that the teeth should stand fairly supported, with the fillings in contact merely and the gold packed so as to make accurate adaptation to the teeth, and contouring the filling accurately to the anatomical lines of the teeth, so that the type of the tooth is reproduced—thereby very largely reducing the chance of caries in the future, and strictly safeguarding the gum.

If you carry that idea in mind, I think

you will all agree that that is the highest type of a filling for the approximal surfaces. If it can be carried out as perfectly as it has been done, you will agree that it is the best that could be accomplished. I think myself that today we are not doing better work than was done then. I doubt if we are doing as good, and I say that very deliberately. In those early days there was an inspiration in dental work which we do not find now, because it was the opening of a new field, and it is not surprising that men with firmness and decision like Dr. Varney should have done such work. Dr. Varney was a man of indomitable will power, and he insisted upon doing every operation as well as he could, whether it hurt the patient or not. I have seen him operate repeatedly where I would not have had the courage to cut as freely as he did. He packed the gold patiently, and very carefully. I have one filling which took him five hours, by the watch, to do. It is perfect, and it is doing good service today, although nearly thirty years since he set it in place. That is perhaps the ideal in dental work. How many of us, in this busy age and under the conditions existing, can always live up to our ideals? It was a kind of work which was a severe tax on the patient and on the operator. It was necessarily an expensive operation, and inasmuch as those perfect gold fillings were put in in teeth that were not perfect, or teeth that were so frail that they would become imperfect in time, it is not surprising that even the best filling would sometimes eventually fail.

So we as dentists are pardonable for seeking some easier way of filling the teeth that will attain the same final results. In all these years we have been struggling as earnestly as any class of men ever struggled for anything they wanted, to achieve some means of saving the teeth more easily and more quickly; some means which would save them as well as was done by that most difficult method of work.

It is not strange, therefore, that we were ever ready to grasp, as would a drowning man at a straw, anything that would help us to bring about this desir-

able result, and at the same time be a saving to the patient and ourselves. It is not surprising that we have dallied with amalgam; that we have striven with gutta-percha; and have struggled and been disappointed with zinc oxyphosphate and in the early days with zinc oxychlorid. We have been watching for some new thing, hoping that we might have something whereby the shapes of the teeth could be restored and sufficient strength for mastication given to all exposed surfaces, without defacing our patients with a great display of any filling material whatsoever.

When porcelain inlays came it was natural that we should almost stand on our heads, and throw our hats in the air, and say "At last we have found what we desired!—something to restore the shapes of the teeth and make them better looking; something we can use quickly and save ourselves the backache and the heartache—which when it comes from the contemplation of the failure of our fillings is worse even than the backache."

Of course it is an easy thing for men in their enthusiasm to be led to extremes, and I presume when we first used the porcelain we were so pleased with its appearance and the ease with which it could be inserted, that we did not stop to realize that it was brittle and inharmonious in a certain way—harmonious in appearance, but inharmonious with tooth-structure, because it was so brittle and so hard and unyielding. Gold has not that hardness, but has almost an elasticity—not like gutta-percha, but something which has made us feel, without stopping to reason it out, that aside from its appearance and its difficulty of insertion, gold is a very harmonious filling material, because of its pliability, if you know how to treat it, if you can get it in place without hammering the life out of it; and it wears down nicely and is swaged to even a better fit by future use.

I am very hopeful about the future, but yet I doubt—provided one takes the time and the patient can bear the strain and pay for the effort—whether we shall ever find anything better than gold in difficult places where the best material

must be used for saving the human teeth.

Gentlemen, do not let us lose our heads while seeking for these new things, and forget the old stand-by, gold—in foil form or in any form used by the early operators who marked the way for us. Of course we know that the operators who preceded that period when Dr. Atkinson's office became so pre-eminent did beautiful work, too; but they had not yet reached the ideal of restoring the shapes of the teeth, and they could not do it so well by their methods. It is no discredit to say of Dr. E. J. Dunning, who was probably the most eminent man of that period—in the presence of two of his relatives here tonight, from whom we hope much—that although he made beautiful fillings he did not restore the shapes of the teeth. Almost the only conversation I ever had with him was at a meeting of the Odontological Society, when he said to me that it was the regret of his life that he had filled the teeth as he did, and he wished he had the opportunity of living his life over, so that he might have more regard for the shapes of the teeth.

I have never been over-confident as to the success of porcelain inlays for the approximal surfaces of the back teeth, or the grinding surfaces to any great extent. I have been more than delighted with their use in the front teeth, where they show, and on the buccal surfaces where not much strain could come.

Years ago it happened that occasionally I observed that amalgam fillings had come out in a solid lump from cavities in which little caries was to be found; and sometimes cohesive gold fillings came out in a solid mass through decay around the fillings, or a breaking slightly of the edge—as it was my custom always to make shallow retaining grooves. This last was partly due to cowardice; I have always been a coward in regard to causing pain, but it is a mistaken kindness, and I would not advise the younger men to follow in my footsteps. They would make better fillings if they cut deeper.

When these old fillings came out, in the haste and hurry of my work, and wanting to do the best I could in a min-

ute or less, I would cut out the decay around the edges, and set the fillings back with cement, saying to myself that while perhaps it was not the most perfect thing that could have been done, it was a good operation, and one that would last many years. And that brings me to the point of saying what I have said to this society before—that I was prepared to be very sympathetic toward the gold or porcelain inlay.

When the idea of making gold inlays after the manner of porcelain inlays was found to be an available thing, I do not know but that I felt more satisfaction than I did at the advent of the porcelain inlay. Porcelain in the front of the mouth for esthetic purposes is invaluable, and I thank God I am alive to see porcelain fillings in the front teeth; for if there is anything I loathe and despise it is the display of gold in the human mouth. Think of it—the human mouth—a place where the best work should be done! Is there any art work that can compare with it? Is there anything more beautiful than to restore the natural appearance of the human mouth? It is art of the highest order.

But where hard work and permanence are required, I firmly believe the gold inlay to be one of the most important developments that have come to us. How little did we think that there was near at hand something that would supplement the advantages of the porcelain filling. While we formerly could do well for the front of the mouth, we can now do equally well for the back, and I am heartily in favor of the gold inlay.

There are quite a number of reasons why it should be hailed with great acclaim, aside from its advantage in this way. Remembering the perfect operations made by Dr. Varney, and considering them as the best—how many of us could make them in this hurried age; and even if we had the time, how many of us have the handicraft to do it? When it comes to the practical care of a practice, where our aim should be to give the greatest service in the shortest time, how many of us are fitted to do that, even if we consider it the best?

There are, however, some strong drawbacks to the gold inlay. It implies a large opening to get the gold inlay in, and severe cutting. In making the old contour fillings with gold, you could work the gold around a corner, or in a deep cavity, without sacrificing so very much of the tooth.

But this is a strenuous age. The older men in the profession realize more fully than the younger men—for their experience teaches them so—that we have to cut our garment according to our cloth. We must do the best we can, and sometimes we have to do mighty poor fillings, and we are glad to do it. I think a man may save a tooth even by doing poor work—the older men know what I mean—for there are some patients who will hardly let you do even “poor” work!

As to the method of making gold inlays: At a clinic before this society I showed a method using crystal gold. I had seen many complicated methods of doing it, and thought we could find a simpler way of getting the occlusion accurately, and likewise the proper contour. It occurred to me that the use of crystal gold placed in the cavity would give us an easy way of getting the contour accurately, as also the articulation; and when I tried that method I found that it was an easy thing—that the gold solder would go through the crystal gold as if it were a sieve. Yet the latter would hold up and keep its shape.

With the ball of the finger press the gold down, then let the patient bite on it, take it out and solder it, and it is done. You hardly have to touch it after that.

Since I showed this method at a clinic before this society, I have seen nothing to weaken my opinion of it. I think it is one of the best ways to get not only the contour, but the articulation. Then I went farther, and made many fillings in grinding surfaces, rubbing the matrix down and filling with crystal gold, and letting the patient bite it into place. Send it down to the laboratory, and you get it back soldered in ten minutes—a beautiful operation. I have used the crystal gold put into cement fillings for many years in a certain class of cases,

then building on to that with foil, and there is no question as to the advantage derived in the filling of frail teeth.

But there is one fault, after all, and that is the necessity of cutting away a large opening to get the inlay into the cavity—because the orifice must be as large as the largest diameter of the deepest part of your cavity, and in a frail tooth there is the danger of cutting too much.

Discussion.

Dr. JOHN I. HART. Dr. Perry has portrayed the necessity for inlay work, so that I shall just take up the technique of making the inlay. The method that appealed to me more strongly was that suggested by Dr. Nyman of Chicago, and more recently demonstrated by Dr. Dills of Brooklyn. To make an inlay by that method requires more time than by the method described by Dr. Perry, but the resultant inlay presents two distinct advantages: one, in that the hollow reinforced inlay contains a mass of zinc oxyphosphate over the pulp; and another, in that this hollowing out gives a much firmer hold to the cement in fastening the inlay into the cavity. The marginal cavity preparation is similar to that advocated by Dr. Black and his disciples.

The interior of the cavity I do not prepare along the same lines. Instead of having sharp or defined angles between the linguo-buccal and axial walls, those lines are more rounded. That facilitates the taking of the impression. If the cavity be very deep, I apply to it vaselin. Small narrow cups, not more than half an inch wide, are prepared of aluminum or platinoid. I always take three impressions, then if one or more of the casts should be destroyed, there will always be an impression to work on. Before dismissing the patient I take a bite in wax. The laboratory man makes up from the mold a fusible metal die, and also from the mold made with the bite strikes a fusible metal die. He strikes up a matrix of pure gold, No. 34 or 35 gage, with a hole punched in the center of it. He also strikes up the outer shell, which is made of No. 22 gold—35 or 36 gage. He

returns to me the outer shell and matrix. These are annealed, and after burnishing the matrix to place, the margins are trimmed quite close to the cavity margins and replaced and burnished; then the outer shell is burnished to place, and the patient is directed to bite in order to test the contour. Sometimes, with the contour pliers, the approximal surfaces are bent outward to increase the contour. These two surfaces, the inner and the outer, are returned to the laboratory man, and he unites the two and finishes them down. I have found it an advantage to solder an extra thickness of gold immediately under the opening in the inner shell, as will be indicated on the casts passed around. This eliminates the danger of grinding through the outer shell. The soldering is done through the hole on the under surface of the matrix. The cervical portion of an inlay for an approximal and morsal surface cavity should be finished before the inlay is inserted, as there is great difficulty in finishing that section of the inlay after it has been cemented to place. Just prior to the cementing of the inlay I make an undercut in the cavity, and when the latter is dry the inlay is cemented to place. I think as little finishing as possible should be done at that sitting, as there is danger, prior to the cement setting stony hard, of upsetting the inlay from the cement if much grinding be done at that time. At a subsequent sitting the margins may be finished so perfectly that an explorer passed over the margins will not detect any appreciable edge.

This inlay principle has so many possibilities that I brought down with me a case of worn or abraded surfaces of the upper anterior teeth. Prior to studying the inlay problem it would have been more difficult for me to restore those surfaces than it has been since. The surfaces, as you see, are worn to a very broad portion of the tooth. The patient being an individual of about sixty-two years of age, the pulp question did not trouble me very much. Two holes were cut into the morsal surface for the insertion of platino-iridium wire, No. 19 gage. The pins were left in the teeth

and removed with the impression. A platinum base was soldered to the pins, and clasp gold to restore the occlusion was built upon it. It is merely an extension of the inlay principle, and I can only say that if the inlay principle helps you out as it has me, you will be very grateful to Drs. Nyman and Hinman and the other gentlemen who have suggested it to us.

Dr. H. W. GILLETT. While Dr. Perry was speaking of those perfect foil fillings, it brought back to my mind a patient who came into my hands when I began practice in Newport, who had been under Dr. Perry's care. Her fillings were made at the time Dr. Perry was still making the Arthur separations between the teeth, so they dated back quite a long time—thirty-five years, Dr. Perry says. They were typical "Varney" fillings.

When Dr. Nyman told us about gold inlays that could be finished so that one could not tell them from the best gold fillings—well, I have a great deal of confidence in Dr. Nyman, but I smiled. It was not very long before a case presented in which I had to have something different from what I had been doing, so I tackled the gold inlays. It was not more than ten days before I began saying that I was through making large gold foil fillings; and since then I have taken an even stronger stand on this point. Those of my patients who have had gold inlays inserted are now unwilling to have foil fillings. In one or two cases, where cavities had been prepared for foil fillings, and by reason of circumstances gold inlays had been made for other teeth in the same mouth, before these large fillings were completed, both the patient and I had difficulty in getting on with the fillings; it seemed very irksome. I say all this with the full knowledge that there will be about a ton of perfectly awful gold inlays made in the vicinity of New York in the next year or two. The same men who make sloppy amalgam fillings, and worse gold fillings, leaving projections of the amalgam and gold sticking into the gum, will make the same kind of gold inlays, and we will shortly hear what terrible damage gold

inlays can do. They can; but gold inlays can be made that will be a great deal better for the tooth than the large fillings that we have been making so laboriously, because we get a support for the walls that we do not get from the foil filling. They can be finished just as perfectly, and with much less strain for patient and operator.

Dr. Perry has spoken fully of the general principles, and Dr. Hart has described the technique of the hollow inlay. I now desire to call your attention to two particular points.

First, however, I want to mention the peculiar adaptability of the inlay Dr. Perry described—the matrix filled with crystal gold and flowed full of solder—for the worn ("cupped") places common in the teeth of elderly people. You know how the best foil fillings are often swaged out of shape in such places. This inlay is wonderfully easy and effective in those places.

My present technique seems to me a little simpler than that described by Dr. Hart. It means more work for the assistant, but less at the chair. Here are some casts of practical cases that will be suggestive to those who have not already begun this work. These are all amalgam casts in which matrices are made for practical cases. I prepare the cavity very much as Dr. Hart described, and take the impression and "bite" at the same sitting. I do not see the patient again or do any more work in the mouth until the inlay is ready for the final fitting in the cavity. After taking the impression as Dr. Hart described, I take the bite in the following manner—taking an approximo-occlusal cavity in a bicuspid as a type: Stop up the undercut caused by the overhang of the adjoining teeth—with a matrix, or a bit of cotton, or in any other way—to permit of low-heat modeling compound being packed into the cavity accurately and withdrawn without dragging. While an impression tray is not needed, a good impression of the cavity is required, and great care should be taken not to let the compound get under the overhang of the adjoining tooth, so that the impression may come away easily. If the case be one

of a single cavity, and the adjoining tooth be a sound one, the matrix is usually essential. Select a narrow one that will not cover the contour or "knuckle" point of the contiguous tooth, and wedge it with cotton against the cervical margin of the cavity. With a large cavity in each tooth, a wisp of cotton to prevent the compound from being forced too far between the teeth at the cervix is usually all that is needed.

The compound cools quickly, and consequently must be packed rapidly. With the electric hot-air syringe soften the surface of the compound, and tell the patient to bite upon it. While I have been doing this my assistant has been warming a "true bite"—a name supplied to this material years ago when it was first furnished to us by the laboratories. It consists of two pieces of a higher-heat modeling compound about three-quarters of an inch long, and a little narrower, and about three-sixteenths of an inch thick—one on each side of laboratory tin foil. Supported in this way, it does not squeeze out of shape as much as happens when the patient closes the mouth quickly. In addition the foil prevents a hole at some critical point.

My assistant brings me the "true bite" as soon as I have allowed the patient to bite into the softer compound. The bite is taken in the ordinary way, the higher-heat compound attaching itself to that in the cavity, and bringing it away with it. The low-heat compound in the cavity will remain soft longer than the other. I frequently use the cold-air blast directed into the imprint of the opposing tooth to chill it after the patient has opened the mouth, and before removing the bite.

The compound comes away very readily, and when the resulting casts are mounted in the small anatomical crown articulators, I have found the result sufficiently accurate to do away with the necessity of seeing the patient again until the inlays are finished. The cast is made of any good alloy. The matrix is made in the amalgam cast, and put into the cavity in the bite casts. The shape of the filling is built up as Dr. Dills has de-

scribed, except that for most cases I find the low-heat modeling compound easier to use than the cement. Then the matrix and built-up compound are transferred to the amalgam cast and the cover matrix is swaged. The hole is cut in the center of the cavity matrix, and the margins of the two matrices are soldered together. The resulting shell is tried in the articulating casts, and any inaccuracy in regard to length or contour is corrected as if in the mouth. I find this process very satisfactory as any assistant becomes more familiar with it. I set one today which did not need to be ground at all, and the patient had not been seen after the impression was taken. The above-described technique enabled me to cover all necessary steps between the impression and the setting of the inlay, without seeing the patient. [Here the speaker exhibited three cases which showed the possibilities of the inlay method which he advocates.]

The other matter I wanted to speak of is in connection with the gold used for this work. In using 24-k. gold for the matrices, and 18-k. solder for filling them, if the occlusion is not just right and requires grinding, a mottled surface will result. The deep gold color will be shown in one part and the white color in another, and the inlay will be unsatisfactory. My own work of this kind is being placed in the hands of a young woman who is very much interested in this particular process, but she needs to have the difficult points simplified. An additional stimulation to my interest in finding a different gold has been the fact that I have a decided preference for gold in the mouth not as yellow as 24-k. My crown work has been done with a whiter gold, approaching clasp gold in color. It is more pleasing to me in the mouth than any other gold alloy with which I am familiar. The result of some experiments which I have had made has been that a matrix gold was delivered to me today—which I think contains one and a half per cent. of platinum—of very satisfactory appearance; also a casting gold or solder which is said to be nearly 24-k., and the color of which is exactly that

of clasp gold. For making a cusp, a piece of matrix gold is pressed into depressions of a die-plate, and filled with the special solder. If the top of such a cusp be ground off, one cannot distinguish the difference in color between the matrix and the solder. That seems likely to be helpful.

I have not had time for testing, but the maker tells me that there is more difference between the melting-point of those two golds than there is between those of 22-k. and 18-k. solder. I tried melting 24-k. gold plate on this matrix gold, and found it could be done. There

is some secret about the preparation of the casting gold or solder which has not been revealed to me. He assured me over the telephone that I might expect the solder to be very free from pits, and that it would flow "like water."

Dr. R. M. SANGER, Orange, N. J. Dr. Hinman called my attention to bridge-making, using inlays as piers. They were made similar to the one described by Dr. Hart. I used an inlay gold made by the Consolidated Dental Mfg. Co., of about 3/1000 of an inch in thickness.

Adjourned.

B. C. NASH, *Secretary*.

Monthly Meeting, October 1906.

A REGULAR monthly meeting of the First District Dental Society of the State of New York was held Tuesday evening, October 9, 1906, at the Academy of Medicine, No. 17 West Forty-third street, New York city, the president, Dr. Arthur L. Swift, in the chair.

Dr. MORRIS I. SCHAMBERG of New York, spoke on the Subject of "Extraction of Teeth a Surgical Procedure."

[This paper is printed in full at page 354 of the present issue of the Cosmos.]

Discussion.

Dr. JAMES F. HASBROUCK. I am glad that I am here before you, and that I have this opportunity to emphasize these facts which have been so ably presented. It is unfortunate, perhaps, that I cannot find some point upon which to differ with our essayist, as that might have made the discussion more interesting; but I am so heartily in accord with all that he has said that I fear the only remarks I can make will be commendatory.

Now, what is an operation, a surgical operation? Our authorities say it is the course of action or series of acts by which some result is accomplished—in surgery, the series of acts and manipulations per-

formed upon a patient's body, as in setting a bone, amputating a limb, or extracting a tooth.

It is a fact that most people look upon the operation of tooth-extraction as being without danger; and most cases are without danger, providing the patient and operator alike are willing to take necessary precautions. You may ask, What are necessary precautions? The answer I can give you in one word—cleanliness—and it would be a good thing if this motto were written in large letters over the door of every dentist's operating room. Of course it must be stated that no surgical interference of any sort is free from danger to life, and a distinction must be recognized between an operation performed to relieve human suffering, and one performed for some cosmetic effect. In the latter case, the danger should enter prominently into the consideration of the propriety of the operation, while in the former case the same danger would have little weight. There are many cases midway between these two extremes, and each must be considered upon its own merits.

The question may arise as to who is in fault when a tooth is broken, and this is a rather difficult one to answer. No one

is infallible, and given a skilful operator, dense process, and irregular or bulbous roots, something must give way in order to accomplish anything, and it is usually the end of a root. In most cases some abnormality is responsible for the mishap, and I cannot see that the operator is at all to blame. As to whether an immediate operation should be performed for the removal of the end of the root, that is a point upon which many arguments are advanced, both for and against. A very important factor is your patient's wish in the matter, although I have found most people tractable when the importance of having the operation completed was explained to them. Mostly, when there is no inflammation and the removal of the end of the root would entail considerable cutting, I favor allowing the end to remain; explaining to the patient that in case of any discomfort arising, the operation can always be performed, but that by waiting a little time, a broken root will always work toward the surface, and can subsequently be removed without any trouble. When a tooth is abscessed, or there is infection of any kind, I consider it most important to remove all broken pieces immediately. Our essayist has demonstrated the value of the X ray as a help to us in diagnosis, and I should like to ask him if in making examinations, he has ever had any trouble from burns?

We must all recognize the value of perfect operative technique, but the inside of the mouth is unique in that it cannot be made absolutely aseptic—only approximately so. But even partial asepsis will achieve very good results, and with antiseptic dressings and washes we can do very well. For any operation, I think the preparation of your patient's mouth is a matter of great importance; true, you cannot boil it or bake it, but by the use of antiseptic washes you can render temporarily innocuous any bacteria which may be roaming about. Another point is the preparation of the operator and his assistant. It is an acknowledged fact that many wounds have been infected by the operator's fingers—so a thorough cleansing of the hands is an im-

portant detail. The matter of sterilization of instruments has been spoken on so often that I do not think any man of ordinary intelligence would think of working in the mouth of a patient with any instrument that had not been properly prepared. After instruments have been used, they should be thoroughly scrubbed with soap and water to clean them of all *débris*, before they are ready to be prepared for the next operation.

In cases of abscess or infection from any source, I favor a thorough curetting of the abscess cavity. After irrigation, the cavity should be packed with iodoform gauze, and the dressing changed frequently, until a healthy granulating surface is established, after which frequent washings will be sufficient. There is a custom I have always looked upon with a great deal of apprehension, namely, that of packing a wound with absorbent cotton. Time and again have I seen this done by members of our profession, and I cannot decry it too strongly. The cotton, moistened by the fluids of the mouth, quickly forms a breeding-place for all kinds of pyogenic microbes, and becomes a menace of the worst kind.

The radiographs shown us have been particularly interesting. The one showing ankylosis of the jaw was especially so to me, and it shows a condition which is somewhat unusual. This I take it was a condition of permanent ankylosis, and operative interference was required for its correction. In daily practice we are most likely to meet with temporary ankylosis, which is a condition of tonic spasm of the muscles of mastication, resulting from irritation of the third division of the trifacial nerve, and inflammatory conditions of the soft tissues. The most common cause is probably the eruption of the third molars; and this brings us to the question of the advisability of the removal of the third molars, which I shall not attempt to answer at the present time, excepting in so far as to say that a tooth should never be extracted unnecessarily, neither should it be allowed to remain in the mouth when its retention involves the health, continued

discomfort, or perhaps the life of your patient.

Dr. JOHN I. HART. We are deeply indebted to the essayist for his presentation to us this evening. He has conclusively demonstrated the diagnostic value of the X ray. While we may deplore the necessity for the other branch of his paper, we must admire his clear presentation of the facts, and acknowledge our debt. Our proceedings are published, and as the conclusions which have been reached by our essayist are the conclusions of every thinking man, they will call the attention of those members of the profession who may not be exercising the precautions he suggests, and which are certainly necessary.

Many of us who have been practicing for some years have gone through different teachings on these subjects. In my early days, I listened to talks from recognized authorities, who suggested the use of cobwebs after operations, and it was not suggested in any jocular way, but just as earnestly as any of the proceedings this evening. There has been a natural evolution from that condition of ignorance to the present knowledge.

Ordinary precautions suffice in some circumstances, but there are conditions in which extraordinary precautions are necessary. Certainly, in the fourth and fifth stages of pericemental irritation the greatest precautions must be exercised before a root is extracted; but in the extraction of a tooth where there has been little or no pericemental irritation, the simplest precautions will secure immunity from injury to the patient.

The essayist has built up an interesting theory as to why at present so many more precautions are necessary for the health of our patients than formerly. His theory seems to be that in the greater efforts that are made to conserve teeth today, we retain teeth which have reached a pathological condition, and have rendered the surrounding tissue less resistant to infection. It may be true. It has seemed to me that in the last few years—say ten years—much greater precautions have been necessary after extracting than were needful years ago.

I did not know whether it was due to atmospheric conditions, or the lack of resistance on the part of the patient. It may be due to the causes he ascribes—a hypercementosis or the general or local inflammatory condition around the teeth. His theory may be correct, and if so it is interesting.

I have found a certain class of cases rather difficult to heal, namely, those in which we have to deal with a very thin alveolar process which had supported two or more roots. This process is liable to undergo a necrotic process, and unless there is a thorough burring away of the septum, the healing in such cases is extremely slow. It seems wise, I think, to anticipate what nature will do, and to remove the septum, so as to stimulate healing by granulation as quickly as possible.

Dr. Schamberg showed on the screen an upper lateral incisor with an abscessed condition around the root, and stated that if that were allowed to heal without curetting, a necrotic condition of the process would be likely to follow. It seems to me that such a condition would permanently interfere with the healing process, unless there was some successful effort made at curetting. In my judgment the necrotic condition existed prior to the extraction, rather than as a result of it.

I want to ask our essayist whether in his estimation, everything being equal, greater precautions are not necessary after the extraction of the lower teeth than after the extraction of any of the upper ones, without taking into consideration any pathological condition of the antrum—I am merely considering the natural drainage from the upper teeth and the natural drainage into the sockets of the lower teeth.

We cannot look for miracles at the hands of our specialists in this department; and where we ask them to extract the roots of teeth that are bayonet-shaped, or hypercementosed, something is bound to give way. They in all honesty make the effort, and if something does give way, even though they have taken all the precautions they should have used.

it is a misfortune, but no fault of theirs; and when we consider the efforts we make to conserve teeth, and some of the fragments we turn over to them to remove, I think the success they meet with should command our enduring gratitude. We should educate our patients that just as we expect them to return to us sufficiently often to conserve the roots of pulpless teeth, so they should return to the specialist as frequently as is necessary, until the sockets are filled with granulations which will protect them from infection.

Dr. M. L. RHEIN. I heartily agree with Dr. Hart's remarks as to the timely need of a paper of this kind for the profession. No one for a moment will oppose the conclusion that the extraction of the teeth is a surgical operation. I believe that is a well-recognized fact; the point is, Has it been so carried out?

During the twenty-six years of my practice I have seen great advances made in all forms of dental work. Notwithstanding some remarks that are occasionally made to the contrary, I believe all of us as dentists recognize that our professional work today is a great advancement over what it was twenty-five years ago. There has been an advance in operative dentistry along every line—with perhaps (up to a very recent time) this one exception as to the practical manner of extracting teeth; this has not kept pace with the other advances in operative dentistry. It has been a slur, in my opinion, upon the practice of operative dentistry, and to some extent a disgrace to us as dentists. It makes no difference whether we general practitioners have done the extracting or whether we have referred the cases to the specialist; I think American dentistry has been far in the rear in the past twenty years on the subject of how the teeth of patients should be removed, when the necessity for such an operation presented itself.

We all know that it is absurd to speak of such treatment of extractions as surgical operations properly performed.

Why has there been this dereliction in the true surgical handling of cases of extraction of the teeth? I speak of our-

selves, the dentists of the city of New York. The main reason, from my point of view, is that most of us have welcomed the opportunity of sending cases of this kind to men who claim to make a specialty of the extraction of teeth, and we at once rid ourselves of all responsibility connected therewith. We tell our patients to go to Dr. J. or Dr. A., and have such and such a tooth extracted, and then dismiss the matter from our minds.

Years ago when extracting teeth was on a par with the removal of corns, it received a fee that was somewhat on the same basis. The fee for extracting teeth seems to have remained the same right up to the present time, and in a city like this it is a most absurd one for such an operation.

What surgeon in New York city could do any operation under anesthesia and take care of the patient in an aseptic manner afterward for two dollars? That is the question in a nutshell. I claim it is our dereliction; it is our fault if we send patients where we know there will be no proper surgical care given. It is not only the aseptic precautions taken before an operation of this kind, but the after-care of a surgical case. Can you conceive of a surgeon performing an operation and then not seeing the case again, or not leaving it under the care of some other surgeon or assistant? It would be an unheard-of procedure; and yet we all know that as a rule this has been the dental procedure in the city of New York during our lifetime.

I claim it is the duty of each individual dentist to realize what is going to be done when a tooth is extracted, and if he does not want to take care of the case afterward, he should see that it is properly taken care of surgically until healthy granulations have covered the wound. This question is one that is opportune, because there seems to be an awakening to the necessity not only of speaking of the extraction of teeth as a surgical operation, but of carrying it out on that basis. Outside of a charity procedure, it is necessary under such circumstances that the patient pay a corresponding fee for a surgical operation.

I do not care whether the tooth happens to be free from infection or not. It may be that only one or two observations are necessary; but in this day of infections, it is essential that every case should be under observation until healthy granulations are distinctly in evidence.

There were some remarks made by the last speaker as to the blame when roots are fractured, etc., that interest me. I thoroughly agree with all Dr. Hart has said. It is absurd for us to blame a specialist because the ends of a root are broken or fractured in difficult cases. When a man uses ordinary precautions and skill, and such a thing happens, no blame should attach to the operator, and it has been unfortunate that a great many men feel they are blameworthy for such a thing. No shadow of blame can attach to a man if he will pursue the manly course in the matter, and inform his patient of the results. But where he deliberately conceals the fact that a portion of the root has been left in the alveolus, he is undoubtedly to be very much blamed, because, as has been well said this evening, there are differences of opinion as to the advisability of leaving in the alveolus the fractured ends of roots.

Dr. Hart has very wisely said that an abscessed fractured end will not give very much trouble by healing over, because, as a rule, it is impossible for it to heal over. There may be exceptional cases where the abscess may be drained through one of the sinuses, the mental foramen or the inferior dental canal, and then heal over; but ordinarily it will not. The fistula is there, and it will remain there so long as any remnant of that root remains in the alveolus. The dangerous cases are those in which the ends of the roots are not infected. They should never be left. Why? Because there the granulations are going to cover them, and encyst them for the time being; but the least disturbance in the health of such patients renders them liable to infection at that point.

Stop and consider that you have in the end of that root the remnants of pulp-material, and you can perceive how

easily infection can take place. It is for this reason that I take the position that the patient should invariably be informed of the urgent necessity for the removal of every portion of a fractured root-end. Of course the patient is always the arbiter as to whether an operation should be done, and if he refuses, that settles the matter so far as we are concerned; but professionally, it is our duty to insist on the removal of all fractured root-ends that may be left in, leaving it absolutely understood as a self-evident fact that there can be no blame attached to an operator because a root has been fractured.

Dr. SCHAMBERG (closing the discussion).

I wish to thank those who have taken part in the discussion of my paper, and also thank the silent members for their attention. I wish to apologize for having presented the subject in a rather disconnected fashion, overlooking points which would have been brought out had I had everything down in black and white.

Dr. Hasbrouck's question in regard to X-ray burns can best be answered by stating that I have made in the neighborhood of five thousand X-ray exposures without having caused a single burn. X-ray work has progressed so much within recent years that pictures are taken in fewer seconds now than it formerly took minutes. In skilful hands, exposures for dental radiographs are practically without danger. Unfortunately, newspapers continue to publish accounts of cases that were burned when little was known about X-ray work. The law is so tardy in meting out justice that cases you read about today are probably those which happened years ago, but which are just now coming to trial.

As to Dr. Hart's question: other things being equal, a tooth-socket in the upper jaw is more likely to heal in an uneventful way, from its being less likely to be troubled by the lodgment of food, and also because of the assistance afforded by gravity for drainage when pus is present. The case described, one in which an upper tooth-socket had healed leaving behind a focus of infection from an ab-

cess which afterward caused trouble about the tip of the nose, was one in which there was no doubt as to the socket having fully healed. This is what frequently takes place when care is not exercised to maintain the external opening until the cavity created by the abscess is filled with healthy granulations.

I am indebted to Dr. Hasbrouck for bringing up for discussion the subject of the fracture of roots, which I inadvertently omitted, though in presenting to Dr. Hasbrouck an outline of what my remarks would be, that point was touched upon. Never do I feel conscience stricken about the fracture of a root. A man who practices the extraction of teeth as a specialty, and endeavors to give each case his best attention, need not blame himself when such a mishap occurs, nor need he have any hesitation about letting the patient know what has happened. Roots at times are so divergent and frail, and the process so dense

that the root gives way before the process. When a fracture occurs the question arises as to whether an effort should be made at once to remove the remaining portion. Only when the end justifies the means are we warranted in subjecting the patient to what may be a most difficult operation. The patient's wishes in the matter must be considered, but inasmuch as the operator is in the better position to judge of the difficulty or ease with which the removal can be accomplished, and what the consequences will be if the part is allowed to remain, the patient should be advised accordingly. If the root is allowed to remain, the patient should be instructed to return upon the first indication of trouble therefrom.

A very hearty vote of thanks was given to Dr. Schamberg for his interesting address.

Adjourned.

B. C. NASH, *Secretary*.

EDITORIAL DEPARTMENT.

THE AMPHOTERIC REACTION.

THAT acids turn blue litmus red and that alkalis restore the blue color to litmus reddened by an acid, and further, that acids and alkalis combine to form salts by neutralizing each other, are facts in elementary chemistry not only well known to students of science but they may be regarded practically as common knowledge. So well established is the belief that any substance which will redden litmus paper is acid, and can be neutralized by any substance capable of turning red litmus paper blue, that the litmus test has come to be regarded as indisputable evidence of the presence or absence of acids or alkalis as the case may be. So generally accepted is the belief in the foregoing data that for many years it has passed unchallenged as to its accuracy.

The careful study of the reaction of the urine, and more recently of the saliva, has brought out the curious fact that in some cases it happens that a specimen of urine will not only turn blue litmus paper red, but will also give a blue reaction

with red litmus paper at the same time—in other words, it exhibits what is known as the “amphoteric” reaction.

Investigation of this curious phenomenon reveals the fact that the acidity of the specimen is due not to a free or uncombined acid, but to the presence of acid sodium phosphate, a salt in which the hydrogen of the phosphoric acid is but partially replaced by the positive element sodium; while the alkalinity of the same specimen is due to the presence of the basic phosphate, in which twice the number of hydrogen atoms of the phosphoric acid are replaced by the positive element sodium;—the acid and alkaline reaction to litmus in the case of an amphoteric urine or other fluid being due to the fact that the two salts exhibiting respectively the acid and basic reactions are incapable of neutralizing each other, which leaves both types of salts free to exhibit their characteristic activities and their respective effects upon litmus. This peculiar phenomenon may be easily studied by mixing solutions of equal strength of the acid and basic sodium phosphates in varying proportions, when, by careful balancing of the quantities used, a point will be reached where both acid and alkaline reactions to litmus will be exhibited by the mixture.

The fact that these two salts are incapable of chemically neutralizing each other is of the utmost importance in the study of the reaction of the urine, and of the saliva as well, for the reason especially, in the case of the saliva, that the reaction of the oral fluids is a factor of fundamental importance in connection with the phenomena of dental caries and likewise of dental erosion. The litmus test alone appears to be wholly inadequate for the purpose of determining accurately the question of the presence or absence of acids or alkalis in the oral fluids. It is inadequate because, bearing in mind the fact that acid salts of sodium and of calcium are capable of exerting a solvent effect upon enamel, and also bearing in mind the fact that the presence of these acid salts in the saliva may be masked or obscured by the simultaneous presence of an amount of basic sodium phosphate sufficient to nullify the litmus test from an optical standpoint, it is therefore necessary to adopt other means than the litmus test, or in connection therewith, to determine acidity of the saliva, and thus learn whether it may be the fact in any given case that even though the specimen may turn red litmus blue there may never-

theless be acid salts present which are chemically capable of acting upon the enamel detrimentally.

The subjoined communication from Dr. Head bears directly upon the subject here discussed. We believe it to be practically impossible to say from litmus tests alone whether a saliva is acid-free or not, in view of the possibility of the existence of unneutralized acid salts in that fluid; we might be almost justified in saying the *probable* existence of these acid salts in the saliva—for certain it is that they very commonly exist in the saliva of arthritics, and their detrimental effect upon tooth-structure is now well known, though to what extent this effect may be modified by other salivary constituents has not been as yet made out.

In view of the reliance which has been placed upon the litmus test in the past, and the confidence which has been reposed in conclusions based upon the litmus test of the oral fluids, we deem it important that this grave source of error in its efficacy should be noted, for in view of its inadequacy as a means for determining the salivary reaction we are of the opinion that all reports heretofore made of the reaction of the oral fluids based solely upon the litmus test are, in the light of the data herein referred to, practically untrustworthy.

Dr. Miller's Litmus Test.

1500 LOCUST ST., PHILADELPHIA, March 19, 1907.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—I should be glad to have some information concerning Dr. Miller's recent experiments and observations on the wasting of tooth tissue, etc.

Two years ago I carried on some experiments concerning the causes of so-called erosions at the necks of the teeth, which, while not nearly so extensive as Dr. Miller's, seemed to lead to the same conclusion—namely, that grit on a tooth-brush is a fruitful cause of so-called tooth-erosion, which under these conditions should be called abrasion.* In addition to this it seemed probable that there might be a chemical cause also in some cases. I have been working with this in view ever since, and have some data that coincide with those of Dr. Miller and some that do not. I have been seriously held back in my work by a difficulty that has not troubled Dr. Miller, viz, the lack of a simple test that will make one assured whether the saliva and mucus of the mouth is really alkaline, neutral, or acid, and to what extent the alkalinity and acidity exist.

Sutton, in his "Volumetric Analysis," page 39, speaks of the well-known

*See *Dental Brief*, vol. xi, p. 279.

fact that a saliva which is neutral to litmus may be acid to turmeric paper and alkaline to lacmoid or Congo red.

In my own experiments I have also found that it may be alkaline to phenol-phthalein under these same conditions. Of course, if the litmus shows a very marked red these contradictory reactions will not appear. As it is known that some salivas will turn blue litmus paper red and red litmus paper blue, this would seem to prove that litmus is not of itself to be relied upon unless it be used in connection with control tests made with other reagents. These tests, so far as the saliva from the parotid, sublingual, and submaxillary glands is concerned, can readily be carried on, as a few cubic centimeters can be so obtained in a few minutes by chewing rubber; but when we come to testing the mucus of the cheek the problem becomes difficult, as it is practically impossible to get enough mucus to boil, and saliva unboiled and containing dissolved carbonic acid is unreliable in giving alkaline or acid reactions with practical sensibility to either litmus or phenol-phthalein; therefore any tests of such mucus with litmus paper have seemed to me most untrustworthy and not to be relied upon. As above noted, such mucus may turn red litmus blue and blue litmus red; and litmus paper when wet with the mucus may look deep blue, and when dried may be neutral or quite red. This possibly is due to the fact that existing CO₂ has been driven off during the process of drying, which also happens when the saliva is boiled. All this brings me to my original question: How can Dr. Miller accurately test the alkalinity or acidity of salivas with litmus alone? Or, if he uses control tests, what are they?

So far as I can discover, Dr. Miller depends simply upon litmus for his acidity tests. In the *Cosmos* for March 1907, on page 228, he says: "The reaction of the mucus of the upper as well as of the lower lip should be taken by lifting up the lip and inserting a strip of blue litmus paper on one side of the jaw and red on the other, leaving it there until saturated. To determine whether the acid comes from the lip or from the gums, insert two pieces of litmus paper separated by any impermeable substance which does not affect the reaction. The reaction should be taken before rinsing the mouth, as in this way only do we obtain true information as to the condition present at that time." [Italics mine.]

I wish to ask you, as one who has done much for dental chemistry, if accurate information as to the acidity or alkalinity of the mouth can be obtained by the litmus test just advocated? The great suggestiveness of Dr. Miller's paper is unquestioned, yet I cannot help feeling that if the technique of his litmus tests are not satisfactorily explained, much of the conclusiveness of his paper will be lost, owing to the inaccuracy of the preliminary mouth-tests on which his experiments are necessarily based.

Yours truly,

JOSEPH HEAD.

A CORRECTION.

WE have been requested by Mr. A. Hopewell-Smith, whose article on "A Study of the Vascular Lesions of the Dental Pulp, Their Complications and Clinical Significance," appears on page 124 of the February issue of this journal, to call attention to an error which occurred in the manuscript of the paper and which remains uncorrected as printed, to wit: The word "atrophic," in the first line, second column, page 139, should read *trophic*.

BIBLIOGRAPHICAL.

THE AMERICAN TEXT-BOOK OF PROSTHETIC DENTISTRY. In Original Contributions by Eminent Authorities. Edited by CHAS. R. TURNER, M.D., D.D.S., Professor of Mechanical Dentistry and Metallurgy, Department of Dentistry, Univ. Pa., Philadelphia. Third Edition, thoroughly revised and rewritten. Octavo, 900 pages, with 916 engravings. Cloth, \$6.00; leather, \$7.00.

The third edition of the "American Text-book of Prosthetic Dentistry" is practically a new book. New not only because the text has been completely revised and greatly amplified by new matter and a wealth of new illustrations, but new in a larger and more important sense in that the entire subject has been treated from an original point of view, so that the theme is developed from a new *motif*.

- Mechanical dentistry has been too long just what the phrase means, mechanical pure and simple, and the intricacies of its multitudinous processes have demanded so much time and mental concentration upon the part of the student that it has produced the unfortunate tendency to regard the mechanics of dentistry as the end of dentistry, rather than to regard mechanics as a means to an end in dentistry. The editor of the "American Text-book of Prosthetic Dentistry" has undertaken to set this matter right, and he has set it right by so treating and arranging his work as to place dental mechanics in its correct and rational relation to dental prosthesis. The book is an epoch-making work—epoch-making because this volume is the first and

only comprehensive treatise in which from first to last a conception of the true purpose and dignity of mechanical dentistry as a prosthetic art has governed the treatment of the subject in all its relations.

The general arrangement of the work is logical, beginning with a consideration of the dental laboratory and its equipment, followed by a discussion of the materials used by the prosthetic dentist, including porcelain teeth and their manufacture. This phase of the work may be regarded as a section by itself, and as preliminary to two chapters that are the real foundations of prosthetic dentistry. There is a chapter by Professor Turner upon The Human Dental Mechanism—its Structure, Functions, and Relations, in which the dental mechanism is studied as a normal or perfect apparatus, and a chapter written by the editor in collaboration with Prof. A. H. Thompson, in which The Modifications of the Dental Mechanism by Age, Temperament, and Use are set forth. In these two chapters the student is brought face to face with the functional conditions that it is his province to restore when by loss of the natural denture they are destroyed or impaired. We know of no similar detailed exhibit of the functioning of the human dental mechanism or one which so comprehensively or lucidly sets forth the engineering features, if we may so express it, of this apparatus and its mode of operation, and we think that the dental profession is distinctly indebted to Professor Turner for not only producing a classic upon this par-

ticular subject, but for supplying the fundamental data upon which to build an intelligent and rational practice in dental prosthesis.

From this point the evolution of the subject proceeds in normal order by chapters upon The Examination, Preparation, and Study of the Mouth Preliminary to the Insertion of Artificial Teeth, written by Dr. H. H. Burchard and Prof. J. P. Gray; Taking Impressions of the Mouth, and The Making of Casts and Their Preparation, by the same authors; then the subject of Dies, Counter-dies, and Molding is treated by Dr. William H. Trueman. After which the subjects of Taking the Bite, The Principles Underlying the Retention of Plate Dentures, and the Selection, Arrangement and Retention of Artificial Teeth are presented in three chapters by Professor Turner.

Vulcanized Rubber as a Base for Artificial Dentures is ably set forth by Prof. George H. Wilson; Swaged Metallic Plates, by Dr. W. H. Trueman; Cast Dentures, by the late Dr. Clark L. Goddard; Continuous-Gum Dentures, by Dr. D. O. M. LeCron. Artificial Crowns, and The Assemblage of United Crowns (Bridge Work) are chapters originally written by the late Dr. H. H. Burchard and now revised to date by Dr. Fred A. Peeso. Dr. Chas. J. Essig's chapter on Hygienic Relations and Care of Artificial Dentures remains under his name, and the work closes with the chapter on Palatal Mechanism by Dr. R. Ottolengui.

Our space limitations make it quite impossible to give anything like a detailed picture of the excellent features of this monumental work, but of this we are well assured—that it presents the subject not only in a new light, but it opens up vistas of scientific interest and scientific possibilities in pros-

thetic dentistry which have not heretofore been realized except by extremely few. It has demonstrated the artistic factor in dental prosthesis, emphasized its possibilities, and has created standards which if intelligently followed will double the debt of humanity to dentistry by adding to its recompense of gratitude for the relief of suffering and restoration of health, additional gratitude for relief from deformity and for the restoration of comeliness.

The work is singularly free from textual errors; some few, however, we have noted which should be eliminated. For example, in Dr. Hodgen's chapter, at page 139, the last paragraph is a quotation taken from page 860 of vol. iii of the "American System of Dentistry," by Litch; it relates to the effect of ignition upon purple of Cassius, and is not only unintelligible in the way the quotation is placed, but it is incorrectly quoted, the introduction of the word "not" completely inverting the meaning of the original. The statement (same paragraph) that "Purple of Cassius is soluble in ammonia before *fusion*," is also misleading and incorrect, as purple of Cassius is not fusible at all, but it decomposes upon ignition—which latter was the word probably intended. At page 306, C. H. Ward is credited with the grading of wear of the teeth into four degrees. This is the system of Professor Broca of the Faculté de Médecine, from whom Ward reproduced the idea.

Some few instances of misspelled proper names occur, *e.g.* J. H. Wassal (page 305) for J. W. Wassall; LaForge (page 434) for Laforgue, the inventor of spiral springs.

The buttressed architecture of the basal support which the cranium gives to the maxillary alveolar border, described

at page 231, is incorrectly credited to H. H. Burchard, who republished the suggestion from A. H. Thompson,* who enlarges the idea from Harrison Allen and Jeffries Wyman; while Fig. 197, illustrating the mandible as a lever of the third class, should have been credited to Burchard, who devised the diagram and executed the original drawing from which the illustration was made.†

The illustrations, which have been greatly increased, are admirable—with a single exception, Fig. 220, which is a silhouette; it should be replaced by a sectional detail view, which would be much more instructive and less difficult of analysis.

Errors of this character are inseparable from the production of a work of this kind, and the wonder is that this one is so remarkably free from them. We congratulate the editor and his co-laborers upon the splendid result of their efforts, and the dental profession upon now having the best work on prosthetic dentistry that has yet appeared in any language.

ANATOMICAL NOMENCLATURE. With Special Reference to the Basle Anatomical Nomenclature [B. N. A.]. By LEWELLYS F. BARKER, M.D., Professor of Medicine, Johns Hopkins University, etc. Two colored and several other illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

It seems unnecessary to review the advantages that would accrue through the adaptation by anatomists, biologists, pathologists, and clinicians of a uniform system of objective anatomical nomenclature. The work now before us—a care-

fully compiled list of anatomical terms—exemplifies the untiring efforts of the host of distinguished anatomists who at the Basle anatomical conference of 1905 presented the results of their labors, extending over a period of six years, in the shape of a rational vocabulary of about 5000 anatomical terms, instead of the 30,000 simple and compound words at present in use by teachers and writers on this subject. To have reduced and simplified the old terminology to about one-fifth of its original volume, without in the least sacrificing the primal object in view, is an achievement for which both students and teachers of the subject must feel deeply indebted to the commission and to Dr. Barker, through whom the matter is now presented to the American world of science.

As bearing more or less directly upon dentistry, we note a number of terms to which we most particularly desire to call attention. In each case the B. N. A. terminology precedes the old one: Mandibular fossa (glenoid cavity); maxilla (upper jaw, superior maxillary bone); anterior surface of maxilla (external or facial surface); mandible (lower jaw, inferior maxillary bone); maxillary sinus (antrum of Highmore); mandibular foramen (inferior dental foramen); mandibular canal (inferior dental canal); canine (cuspid); premolars (bicuspid).

In the portion of the book devoted to anatomical dental terminology, we find terms which we trust may be substituted by the more accurate ones in a future edition. We refer to "chewing surface" instead of *occlusal surface*; "foramen of apex of tooth" instead of *apical foramen*; "smaller dental canals" instead of *dentina! canaliculi*; "superior dental

*DENTAL COSMOS, vol. xxxv, p. 594.

†Burchard, "Dental Pathology, Therapeutics, and Pharmacology," p. 173.

arch" instead of *upper dental arch*, and "inferior dental arch" instead of *lower dental arch*.

The historical chapters at the beginning of the work, by the editor, are deserving of a special word of commendation,

and there, as well as throughout the book, he has displayed that degree of care and editorial attention which necessarily leads to the production of reliable works.

J. E.

REVIEW OF CURRENT DENTAL LITERATURE.

Conducted by JULIO ENDELMAN, D.D.S.

[*L'Odontologie*, Paris, February 15, 1907.]
ON THE SEPARATION OF PLATINUM, GOLD, AND SILVER FROM A MIXTURE OF LABORATORY FILINGS. BY L. LEMERLE, PROFESSOR AT THE ÉCOLE DENTAIRE OF PARIS.

The method about to be described of separating platinum, gold, and silver from laboratory filings is the one followed by a well-known Parisian firm of assayers. The quantities of the different chemical reagents and substances given throughout this review are the quantities to be employed in treating a weight of filings of about 100 gm.

Dissolution. Place in a glass globe of one-liter capacity the quantity of filings to be treated and a mixture of 150 gm. nitric acid C. P. and 450 gm. hydrochloric acid. Heat the globe over a dull fire or in a sand-bath.

Evaporation. When the filings have been dissolved pour out the contents of the glass globe into a porcelain dish, and evaporate the fluid slowly to a syrupy consistence. Now add to the syrupy fluid 100 gm. of hydrochloric acid, and cover the dish with a funnel to prevent any portion of the liquid from splashing out on account of the active reaction which takes place upon the addition of the hydrochloric acid. When the reaction is completed, evaporate the solution as in the previous case, to expel the excess of acid.

Separation of silver. Add to the liquid 300 gm. of distilled water, and heat for about one hour in order to complete the precipitation of silver chlorid. Filter, and collect the filtrate in a glass of 750 ccm. capacity.

The precipitate of silver chlorid which remains in the filter is washed three or four times with boiling water, and this water is added to the filtered solution.

Separation of platinum. To the filtered solution 150 gm. of pulverized ammonium chlorid are added, and the contents of the glass are stirred with a glass rod and allowed to decant for at least six hours. The platinum will now be found precipitated in the form of chloro-platinate of ammonia. The platinum precipitate is now collected by filtering, and is washed with 200 gm. of cold water to which 30 gm. of sal ammoniac have been added. The platinum precipitate and water are again filtered and the liquid is collected in a glass receptacle of one-liter capacity.

Separation of gold. In the latter receptacle, 100 gm. of crystals of ferrous sulfate are dissolved, stirring the mixture from time to time with a glass rod, and allowing it to decant for eight to ten hours. The gold is slowly precipitated in the form of a brownish powder. The contents of the glass receptacle are now filtered in order to collect the brown powder, which should be thoroughly washed, as in the case of the silver chlorid.

The separation of the precious metals being now completed, it remains to convert the products thus obtained into metallic form.

After having been completely dried, the silver chlorid is placed, together with the filter in which it is held, in a crucible, where it is fused with a mixture composed of three times its weight of sodium carbonate and

four per cent. of its weight of charcoal. After the mass has been fused and cooled, the crucible is broken and the silver ingot is removed. The chloro-platinate of ammonia is detached from the filter and the paper is burned in a porcelain dish, in order to collect the small particles of platinate that may have remained attached to the paper. Into the same porcelain dish the platinate is placed and calcined, heating the dish slowly and progressively and carrying it eventually to a white heat, at which point it should remain until the evolution of white fumes has ceased. The gold is treated by the same process as described in the case of silver, with the exception that instead of the sodium carbonate and charcoal mixture it is fused with three times its weight of borax and once its weight of saltpeter.

POINTS ON THE TREATMENT OF STOMATITIS. BY DR. RAOUL LABBÉ.

Dr. Labbé (*Rev. des Connaissances méd.*, April 15, 1906) discusses the treatment of stomatitis as follows:

(1.) An attack of stomatitis, of whatever form it may be, requires general hygienic and dietetic treatment, which must necessarily vary according to the degree of contagiousness of the attack.

(2.) When the attack is of enanthematous nature, the patient should be isolated during a period which should be made to vary according as to whether the attack is one of impetigo, thrush, ulcerous stomatitis, etc. Each tetter should be antiseptically treated, and if the patient be an infant who is being fed from the mother's breast, the latter should be likewise antiseptically treated.

(3.) In infants fed on the mother's milk, such forms of the disturbance under consideration as thrush and exfoliative stomatitis are rare, but those fed on cow's milk, in addition to these forms of stomatitis, may also suffer from the aphthous variety, which may be transmitted to the infant from a cow suffering from aphthous fever.

(4.) The mouth should be frequently irrigated with alkaline one per cent. solutions of either potassium chlorate, sodium borate, or sodium bicarbonate, or swabbed with either of these agents in stronger solution—say five

per cent. In addition, the use of the following mouth-washes are recommended:

R—Sodii hyposulphatis, gr. lx;
Glycerinæ,

Aquæ destillatæ, āā ʒij. M.

Sig.—To be used as a mouth-wash morning and evening.

R—Sodii biberatis,
Potassii chloratis, āā gr. lxxv;
Aquæ destillatæ, ʒij. M.

Sig.—To be used as a mouth-wash in cases of severe stomatitis several times a day.

Against the fetidity of the breath either a solution of potassium permanganate 1:1000 or dilute hydrogen dioxid solutions may be employed.

(5.) The general condition of the patient should be given proper attention, especially if he be of the cachectic diathesis. In such cases, the administration of purgatives is strongly indicated.

[*Le Laboratoire*, Paris, January 13, 1907.]
A GLASS SOLDER. BY CH. MARGOT.

M. Margot states that an alloy composed of tin 95 parts and zinc 5 parts, which melts at 360° F., adheres to glass tenaciously, and possesses an unalterable metallic luster. An alloy of tin 90 parts and aluminum 10 parts, melting at 572° F., also adheres strongly to glass surfaces. By means of either of these formulæ two glass surfaces can be united as if they were of metallic composition.

[*La Odontologia*, Madrid, February 1907.]
ON THE ACTION OF GENERAL ANESTHETICS. BY DR. NABIAS, BORDEAUX, FRANCE.

The author (*Journal de Méd. de Bordeaux*) has carried on a series of investigations in view of determining, if possible, the nature of the action of general anesthetic agents. He describes in detail the experiments which have led him to conclude that anesthetics act by inducing dehydration of the nerve cells. In view of this conclusion, and in order to preclude the possibility of the anesthetic dehydrating the nervous protoplasm to a degree at which functional activity could not persist, Dr. Nabias recommends first that the agent should be administered slowly and

carefully, and second, that the patient be made to drink a large glass of water every half-hour for at least six hours before the time set for the anesthesia. This preventive measure originated by Denucé has been productive of extremely satisfactory results, and in the cases to which it was applied by him—at least twenty—not only was there complete absence of ill effects during the administration and subsequent operation, but likewise not even the slightest post-operative vomiting or nausea.

[*Archives de Stomatologie*, Paris, November 1906.]

ON THE FUTILITY AND DANGER OF TREATING COCAIN POISONING WITH MORPHIN. BY DR. VAILLARD.

It was by observing that morphino-maniacs possessed a high degree of tolerance to the effects of cocain that Magnan-Chauppe was led to experiment with morphin as an antidote to cocain. These two agents induce physiological effects of opposite natures, and as was pointed out by Laborde, a fatal dose of cocain has not resulted in death when administered following the injection of a dose of morphin. But, unfortunately, the antagonizing therapeutic effects of morphin are not so pronounced when the agent is administered in severe cocain poisoning, namely, after the effects of the latter alkaloid have fully developed. Pouchet, who has studied the question, is of the opinion that while atropin, chloral, and chloroform are capable of decreasing the intensity of the convulsive paroxysms in cocain poisoning, morphin either stimulates them or decreases them (uncertainty of action). Consequently, Pouchet recommends the rejection of all narcotics in the treatment of cocain poisoning. Chloral, of course, is, to a certain extent, an antidote to cocain by virtue of its vaso-dilator action; but in this connection it must be borne in mind that while certain symptoms may be attenuated, the toxic action of the partial antidote will render the toxic effects of the original poison still more pronounced.

A case of fatal cocain poisoning, reported by Lacassagne and Rolland in the *Archives d'Anthropologie criminelle* for January 1905, shows that morphin, at least in that particular case, hastened the fatal termination.

Until more careful studies of cocain poisoning shall have been made, it would be well, in Mr. Vaillard's opinion, to limit the treatment of cocain poisoning to inhalations of oxygen. Such agents as chloroform, ether, and amyl nitrite should be employed with the greatest caution, if at all.

[*L'Odontologie*, Paris, February 28, 1907.]

DENTAL ECTOPY AND NASAL SUPPURATION. BY J. SORDOILLET, INTERNE OF THE HOSPITALS OF NANCY.

The essayist discusses the relationship between dental disturbances and pathologic phenomena in organs which to all appearances are, from an anatomic and morphologic viewpoint, independent from the oral tissues to which the origin of the disturbance may be eventually traced. In the presence of a nasal suppuration, after excluding infection of the maxillary sinus, one would hardly be inclined to search for the etiologic cause in the teeth or surrounding tissues. However, an interesting case in the service of Professor Jacques has recently come under M. Sordoillet's observation, which not only illustrates the pathologic enigma under consideration, but in addition points out the irrefutable fact that none of the specialties which are designated collectively under the term medicine can be, strictly speaking, considered in the light of isolated branches of the mother profession. The dentist who fails to recognize the relations of his specialty to those of otology, ophthalmology, rhinology, laryngology, and *vice versa*, and the practitioner who devotes himself almost exclusively to the treatment of gastric, pulmonary, and other diseases in which the issues of life and death are more salient, and who similarly neglects to dispense a fair degree of observation to the conditions coming under the headings of the above enumerated specialties, are working in semi-darkness that is the more deplorable because of its possibly evil, if not fatal, effects upon the lives of those under their care. In these days of so-called rational therapeutics, for a practitioner to make a diagnosis of any pathologic condition in which all possible etiologic factors involved have not been duly weighed, whether within his own field of action or far beyond the boundaries of his specialty, is comparable

to the often-quoted speculations of the imaginative knight-errant immortalized by Cervantes, when mistaking the windmills for a gigantic soldiery on the ground that the revolving "arms" could be but the upper extremities of animate things.

The clinical case and *raison d'être* for the above remarks was as follows: M. H., age forty-five years, complained of a respiratory difficulty on the left nasal side, of several months' standing, and complicated during several weeks past by a pyogenic discharge from the nostril of the corresponding side. At irregular intervals he would perceive a certain fetidity. About a month prior to his consulting M. Sordoillet, an abscess developed on the left side of the palatal vault and a little beyond the median line. The phlegmon disappeared without spontaneous breaking or surgical intervention. The patient did not complain of pain in the nose, but at times had suffered from pain above the socket of the upper left canine, which several months previously had been extracted for reasons not stated by the author. The intermittent pain was accompanied by a recrudescence of the nasal discharge. An examination of the mouth revealed a generalized inflammation of the mucous membrane, the presence of many roots, and of fragments of roots. The remaining sound teeth were in irregular and abnormal positions. Behind the upper left first bicuspid—a healthy tooth to all appearances—a fistulous tract was discovered into which an explorer could be introduced and carried backward for a distance of 15 mm., when it would encounter a hard, unyielding surface. In the left nasal cavity, and at a point corresponding with the location of the mouth-fistula, a painful and bleeding swelling could be detected which communicated with the fistula opening into the mouth. Under chloroform all defective and diseased teeth were removed, and the palatal mucous membrane was dissected backward from the median line to the first bicuspid. The region corresponding to the internal wall of the alveolus of the left canine was the seat of a severe osteitis. The area was thoroughly curetted to a point opposite the left central incisor, where a sound tooth was found lying in a horizontal position, with the apex within the maxillary sinus. The

tooth was removed, and the wound having been properly treated, the patient very soon recovered, and, as may be surmised, was not again inconvenienced by a nasal discharge.

[*L'Odontologie*, Paris, February 28, 1907.]
ON A NEW METHOD OF TREATING PERICEMENTITIS BY MEANS OF LOCAL INJECTIONS OF SODIUM SALICYLATE.
By D. MARGERY.

In the February 1907 issue of *La Revue de Stomatologie*, the author describes his adaptation to the treatment of pericementitis of the method suggested by Professor Bouchard for the treatment of acute articular rheumatism by means of injections of sodium salicylate *in loco dolenti*, and applied to dental surgery by Dr. G. Lemerle. The quantity of sodium salicylate in two to three per cent. solutions to be injected varies from one to two cubic centimeters, according to the size and number of roots of the affected tooth. This treatment should be instituted as an auxiliary measure, and only in cases in which the ordinary methods of treatment have failed to relieve the intensity of the symptoms. In the presence of extreme pain the method under consideration is particularly indicated, but the reader should bear in mind the important fact that the injections are not altogether devoid of danger, for among the cases reported by Dr. Margery we find two in which the operation was followed by sphacelus, which in one case led to the elimination of an alveolar sequestrum. The injection may be performed either in the gingivo-buccal groove or in the neighborhood of the gingival margin. The contents of the syringe should be slowly expelled.

[*Archives de Stomatologie*, Paris, November 1906.]

A CASE OF SYPHILITIC LESION OF THE TEMPORO-MANDIBULAR ARTICULATION. By DR. W. STERLING.

The essayist describes the case of a man aged twenty-five, who on account of a lesion in the temporo-mandibular articulation experienced such difficulty in opening the mouth that he was prevented from taking solid nourishment. The onset of the morbid phenomena had been marked by pain, at first in the left articulation, and fifteen days afterward in

that of the right side. The clinical history of the patient showed that five years previously he had contracted syphilis, and that after the appearance of the characteristic roséola had been started on a specific cure, at the conclusion of which he found himself so far recovered that no additional treatment had been found necessary. Since that time, up to the onset of the disturbance under consideration, no sign of the chronic lesion had been further perceived. Upon examination of the painful area, a tumefaction was found in the maxillary bone near the zygomatic arch, involving the lower portion of the temporal region and the temporo-mandibular articulation. Upon palpation it was discovered that the malar bone and the zygomatic arch on the affected side were decidedly thickened.

In view of the data furnished by the clinical history of the patient, of a total absence of organic lesion and of an almost normal urine, the diagnosis of syphilitic manifestation was reached, and subsequently confirmed by the rapid amelioration of all the symptoms, and complete recovery following a mixed specific treatment.

[*Therapeutic Gazette*, Philadelphia, February 15, 1907.]

MOUTH-DISINFECTION. (EDITORIAL.)

The *Therapeutic Gazette* called attention several years ago to the necessity of paying due attention to the condition of the mouth prior to the administration of ether or chloroform for the production of surgical anesthesia, pointing out that the pulmonary complications which follow the use of these drugs on certain occasions are chiefly due to the inhalation of pathogenic micro-organisms which when in the mouth are incapable of much harm, but which in the lung create severe disease. When it is considered that the pneumococcus is found in nearly every so-called healthy mouth, and that many other organisms are associated with it, it is rather remarkable that pulmonary infections are as rare as they are. An interesting research to determine the best methods of disinfecting the mouth, particularly in reference to pneumonia, has been published in the *Journal of Infectious Diseases*, October 30, 1906, by Wadsworth.

He used a considerable number of substances as mouth-washes, and made culture experiments from the mouth to determine the bactericidal value of his measures. It is interesting to note that in his experience most of the mixtures or substances used at the present time as mouth-washes possess very little if any true disinfectant or germicidal power, whereas normal salt solution or ordinary alkaline solutions are efficient in destroying pneumococci. He also found that none of the so-called commercial solutions are efficient when tested upon pneumococci under conditions supposed to be most favorable for their action, and that even such active disinfectants as formalin, lysol, and hydrogen dioxide failed to act on the pneumococcus in exudates. It is also interesting to note that alcohol alone of all the antiseptics proved efficient when tested on the pneumococci under all conditions. Again, Wadsworth found that the rapid diffusion of alcoholic solutions was greatly accelerated by the addition of glycerin. In other words, cleansing the mouth with a normal salt solution simply cleanses it, but does not destroy the bacteria, whereas washing the mouth with an alcoholic wash containing 30 per cent. of alcohol actually produces true disinfection, particularly if to the 30 per cent. solution of alcohol in water a small quantity of glycerin and salt is added.

It would seem evident that this investigation possesses great practical importance, since it enables us not only to prepare patients for operation in such a way that pulmonary complications can be largely avoided, but also because it helps us to prevent the spread of acute infectious diseases, such as pneumonia, from one individual to another, the spread being most frequently induced by small particles of sputum laden with the pneumococcus being expelled in coughing or sneezing, and so finding a way to reach healthy individuals. In hospital wards we are learning that epidemics of croupous pneumonia not infrequently arise after the entrance of a single patient suffering from this disease, and Wadsworth's investigations provide us with a most valuable means of prophylaxis.

PERISCOPE.

To Prevent Expansion of Plaster.—If slaked lime is added to boiling water, and the clear liquid decanted for use in mixing plaster of Paris, the plaster will not expand.—P. B. McCULLOUGH, *Dental Brief*.

Aluminum Washers.—Aluminum plate makes washers where you want a close joint. It is better than lead on a vice where you wish to protect what you are gripping.—A. G. KNIGHT, *Commonwealth Dental Review*.

Hydronaphthol as a Pulp-capping.—To avoid the removal of the layer of softened dentin, which, if removed, would probably necessitate the removal of the pulp, mix equal quantities of hydronaphthol and cement, and place as a capping on the layer of decalcified dentin, allowing it to set. Then proceed with the filling. The hydronaphthol arrests bacterial action.—A. W. MCCALL, *Federal Dental Journal*.

Chloroform Water as a Hemostatic.—This is used by Spaak (*Journ. de Méd.*, September 16, 1906), who finds it superior to all other styptics. It acts with marvelous rapidity, has not the slightest disagreeable taste or odor, is not escharotic, is easily obtainable, and can be made as required. It is not unpleasant when applied, and does not interfere with the surgeon in his operations. Spaak recommends a two per cent. simple solution in water.—*Medical Times*.

Three Useful Pointers.—To take vulcanized rubber from teeth taken off plates.—Place teeth in a small, wide-mouthed bottle containing chloroform, over night. The rubber may be removed as easily as so much charred cork.

To keep hypodermic needle always ready for use. After using, unscrew the needle from the syringe, and blow out any liquid that may be in it. Place a drop or two of alcohol in the large end, and force it through with breath pressure. Use no wire, and do not connect the needle with the syringe until wanted. When so treated, the needle will not clog.

Handy and tough broaches may be made by filing fine piano wire to proper size. Taper

by leaving the broach four-cornered. Such a broach may be used for reaming out the smallest nerve-canal without danger of breaking the broach. Different sizes may always be kept on hand. For posterior canals where the holder cannot be used, a knob may be put on the end with a little soft solder, using zinc chlorid. This is convenient in rotating between finger and thumb to enlarge canals. Piano wire may be obtained from any piano tuner.—J. WYCLIFFE MARSHALL.

To Hasten the Solution of Gutta-percha in Chloroform.—Chloro-percha becomes un-serviceable now and then when it is much needed, because of loss of chloroform through evaporation. To get it into shape again for immediate use, add the solvent and immerse the container in a dish of hot water. The chloroform begins to boil forthwith, and the material is ready for immediate application.—*Dental Office and Laboratory*.

Putrescent Pulp.—I have found the following formula convenient in treating putrescent pulps:

℞—Thymol,
Menthol, āā gr. xxv.
Mix until liquefied.

In treating cases of odontalgia the following has been successful:

℞—Chloral hydrate,
Camphor, āā gr. xx.
Mix until liquefied.

—C. E. ABSTEIN, *Dental Review*.

Sterilization of Engine Handpieces.—Dr. Viggo Andresen of Copenhagen, Denmark, recommends for the sterilizing of engine handpieces and other instruments the heating of them in paraffin oil to a temperature sufficient to destroy all bacterial vitality in connection therewith. Dr. Andresen states that steel instruments, as well as vulcanized attachments thereto, can stand heating up to 150° C. without unpleasant results. The method suggested has the advantage of causing no injury to the surface of the steel by oxidation or corrosion, as when water or aqueous solutions of various antiseptic agents are employed for this purpose.

Application of Silver Nitrate.—Silver nitrate should be employed with a great deal of care. We should not use it in very deep cavities where there is danger of irritation of the pulp. It is in the beginning of caries of the teeth that it is especially useful. I crush a crystal of silver nitrate on the glass slide used for mixing cement, and put a drop of water on it; stir it for a moment, then touch the end of a toothpick to it and carry it to the cavity with that, having first dried the cavity. If possible, let this application dry in the sun, and within fifteen minutes the silver will be precipitated and will become black; if not so at the first sitting, repeat from time to time until a thoroughly black surface results.—G. V. BLACK, *Dental Review*.

A Method of Handling and Sterilizing Root-canal Broaches.—To begin with, broaches come into our hands through the retailer, who, in his turn, gets them from the manufacturer, and neither of these knows or cares much about the sterility of the broach. We are all familiar with the usual manner in which the broaches are put up—six in each flat package, each broach in its respective groove, and all held in place by a narrow strip of paper pasted across the whole six, the entire width of the package. Did you ever watch an average practitioner open a new package of broaches, and pull an individual broach from the package when needed? Almost invariably, I dare say, he takes hold of the smooth end of the broach and pulls it out against the barbs, thus not only dulling these fine barbs and practically destroying their efficiency, but also gathering on them a quantity of paper. An examination under the microscope shows how effectively this adherent paper serves to stop up the grooves, and so to shorten the lengths of individual barbs. These foreign particles we are often able to see with the naked eye; but being unable to remove them without destroying the sharpness of barbs, we let it go at that, many times introducing and leaving such foreign particles within the canals. Of course, to remove the strip of paper that holds the broaches in the package and lift out each broach with a foil-carrier, taking hold of each of them a little back of the beginning of the barbs, would be the better way; but here, again, we get into trouble—the other broaches fall out and scatter here and there, gather dirt, and dull the barbs. The question seems to resolve itself into just one thing; we must have some closed receptacle into which we can place the broaches after having carefully lifted them out of their beds in the broach package. They must be kept in this recep-

tacle, clean and without deterioration, and must not be uncovered except when needed. To this end I have succeeded, to my own satisfaction, in devising the following scheme, which I offer to the profession as a better one than that of boiling the broaches, or any other method of sterilization I have ever attempted or of which I have heard. This method certainly does not destroy the sharpness of the barbs, nor does it impair their temper—both very essential qualities in a broach. Select two wide-mouthed bottles with interchangeable ground-glass stoppers, one of which should have a flat top and a hollow inside. Into the hollow stopper fit a cork tightly, and use a vulcanite file to trim the diametrical excess. Open two or more packages of broaches, lift out each broach carefully from its bed as suggested before, and push each into place in the cork. Have the barbed ends reach to as nearly as possible the same horizontal plane. Then pour in the bottle enough carbolic acid to just cover the barbs nicely, and label the bottle. Into the second bottle pour a quantity of absolute alcohol. When the broaches are needed, take out the stopper with broaches from the carbolic acid bottle, and transfer it to the alcohol bottle. Shake a minute or so to neutralize the action of the carbolic acid, and the broaches can then be used with the assurance that there is nothing on them that might be apt to give trouble. The advantage of a flat base in a glass stopper is obvious; it can be set down on the bracket table, and it will not roll about. Replace the empty punctures in the cork with new broaches, and again immerse the whole in the phenol bottle for further use. When the phenol discolors, showing signs of deterioration from age and exposure to light, change it for a fresh quantity, and be sure to keep it in the dark corner of your medicine cabinet.—GEORGE ZEDERBAUM, *Dental Brief*.

Care in the Use of Silver Nitrate.—In the use of a strong solution of silver nitrate it is necessary to neutralize any of the solution which escapes from the confines of the area intended for its reception, for silver nitrate solutions, except the very weak ones, are escharotic. For that purpose I am in the habit of flushing out the mouth with a solution of common salt, say fifty per cent., but almost any strength will do. In that way insoluble silver chlorid is formed. Silver chlorid when dry has a sandy consistence, so that it should be well washed out of a cavity. For erosions or exposed surfaces where the action of the silver nitrate must be limited,

I am in the habit of using the stick, or "lunar caustic."

Another combination of silver nitrate is that with iodine, forming the insoluble, soothing silver iodide. This is done by first applying tincture of iodine liberally over the gums and about the teeth, but not in the cavities, for the teeth will become discolored; then apply about ten per cent. silver nitrate solution immediately on a small swab, and follow this with some more iodine, which prevents any free silver nitrate remaining, and although there is a surplus of tincture of iodine, it may be quickly washed out, and is at the worst merely irritating. This application I use frequently, especially after cleansing the teeth, and in the treatment of all infectious conditions of the gums and oral cavity.—OTTO HOLINGER, *Dental Review*.

Cavity Preparation for Inlays Subject to Stress.—In the preparation of a cavity for an inlay which will be subject to stress of mastication, we must ever keep in mind that the inlay must be retained primarily by the mechanical relation between tooth and inlay. This should be laid down as a basic principle, and can be accomplished only by a close study of the direction and amount of force to which the inlay will be subjected. No one set rule for cavity preparation will serve for all cases, but in many instances the method of procedure must be left to the best judgment of the operator. Since so many similar cavities occur, however, under similar conditions, a few general rules may be given which in the main would be safe to follow. In all classes of cavities the general form should be such that when the greatest stress of mastication is brought to bear upon the inlay, it will be met in the cavity by sufficient mechanical resistance to prevent its dislodgment. When this form of cavity is secured, that stress will tend to more firmly lock the inlay in the tooth. The theory of "extension for prevention" must be observed, but since gold inlays are especially applicable to extensive cavities, this principle is necessarily carried out in all such cases. In general, the cavity preparation should be much the same as for a gold filling, with certain exceptions. All undercuts and perpendicular walls should be avoided, and the axial walls should form a slightly obtuse angle with the pulpal walls and the seat of the cavity. This technique does not necessitate the beveling of the enamel margins, as the enamel rods at the margins will then be supported by sound dentin. If the margin of a cavity is in close proximity to the summit of a cusp, it should be carried

well beyond that point, to admit of a sufficient bulk of gold to withstand the stress likely to be brought upon it, and thus protect the enamel margin. This can be accomplished nicely by the use of suitable stones and sandpaper disks. In approximo-occlusal cavities the occlusal portion of the cavity should be carried well over that surface of the tooth, to allow a decided dovetailing into a strong portion of tooth-structure. Too great stress cannot be laid upon occlusal retention for such inlays. It is the only reliable retention in this class of cavities, and yet in many instances it is, by some operators, entirely overlooked. The angle formed by an approximo-occlusal margin should be well rounded by means of stones and sandpaper disks, as this is a point on the cavity margin liable to fracture under stress of mastication, if left unprotected. The angle of the step should be strictly rounded to facilitate the adaptation of the matrix. All the peripheral margins should be nicely polished with sharp burs, Arkansas stones, and fine disks, until a smooth, clean-cut outline is presented.—W. D. N. MOORE, *Dental Review*.

The Cement Line of Inlays: Permanence Dependent upon Minimum Thickness.—When an inlayed filling is made to perfectly fit a cavity (which is quite possible) and is properly cemented to place, the cavity is so sealed that a leaky condition such as occurs about an ordinary metal filling is impossible. The permanence of a cement line about an inlay is dependent to a great extent on its minimum thickness, both for strength of adhesion and diminished tendency to wear away. Comparing this cement joint to the wood-joiner's glue joint, the minimum amount gives the maximum strength, and it must be remembered, too, that cement is much stronger than glue. The closer the inlay fits against the walls and margins of a cavity, the less cement is exposed, and in consequence there is less to wear and wash away. The way that cement wears (cupping out) when used alone as a filling, allows of certain comparisons. It has been my observation that cement wears out, from the margin of an inlay, only as deep as the margin is wide, and no deeper. I consider this, if correct, a very important fact in inlay work. So I repeat, if an inlay is made to come in close contact with cavity walls and margins, there is practically no cement to waste away, and if it does wear it is only to a depth as great as the margin is wide. This explains to me one of the principal reasons why inlayed fillings

are less subject to recurrent caries.—S. J. KNOWLES, *Dental Review*.

Method of Mixing Cement.—There should be just enough powder added in small portions to the liquid, thoroughly spatulating each portion, until a homogeneous mass is formed. For fillings it is best to mix it as stiff as possible; for crowns, bridges, and inlays, as stiff as will permit of the piece going to place. Too little spatulation gives a quick-setting, granular result, and over-spatulation gives a cement which will never properly crystallize. All cements have their peculiarities, and before any one is used a perfect comprehension should be had of all its peculiarities by experimentation out of the mouth. The method of incorporating as much powder as possible in an effort to produce a very stiff or putty-like mix that can be kneaded between the fingers is to be condemned, not only from the fact that an imperfect mix is obtained, but also because the water of crystallization will be absorbed during contact with the fingers.

In mixing cements I have found a large porcelain slab, in combination with a large, thick, almost convex-shaped metal spatula, best adapted for the purpose. The slab and spatula should be immaculately clean before commencing to mix, if for no other reason than the fact that one crystal of a kind will hasten the formation of other crystals, thereby in the end ruining or very much impairing the usefulness of the cement after mixing.—ROBERT HOMER WELSH, *Items of Interest*.

Successful Partial Lower Dentures.—

In the application of partial lower dentures much possible injury may be easily avoided, and a hygienic and satisfactory result obtained by a modern type of construction. This embraces the use of a wire of clasp metal, or iridio-platinum, of No. 12 to 14 gage, adapted to conform to the outline of the anterior part of the arch at a point well down toward the floor of the mouth. Where the bases are of gold or platinum, the ends of the wire should first be flattened on the anvil, bent to come in contact with them, and then securely soldered thereto; while if vulcanite is to be used, it is only necessary to flatten and notch the surplus end, and to have it sufficiently long to insure adequate attachment, and thus preclude the possibility of subsequent loosening. If clasps be used, they should be first soldered to the wire, using an extension of the same size wire for

this purpose; a single anterior tooth may also be supported in the same manner. Such a type of construction—whether used in conjunction with clasps or not, and whether the case be made of platinum and porcelain, gold, or aluminum with vulcanite attachments, or simply of vulcanite alone—does not materially increase the length of time required to construct the denture or the expense involved, but will be productive of results which will be difficult to obtain in any other manner, and which will be appreciated by the wearer from the very beginning to the very end of its usefulness.—HART J. GOSLEE, *Western Dental Journal*.

Contraction and Expansion of Plaster of Paris.—

When dental plaster of a good quality and water are mixed in proper proportions, re-crystallization or setting usually begins in from two to six minutes. At the initial stage of the setting process a very slight amount of contraction is noticeable; then follows a short period of inertia lasting a minute or two, after which expansion sets in. The expansion begins slowly, then increases rapidly, until in about four or five minutes the maximum rate of movement is reached, when it gradually decreases, and is apparently over in about twenty minutes from the time of making the mix. As a matter of fact, expansion to a limited extent continues for twenty-four hours, or even a longer time, with no perceptible contraction following. During the setting process a rise of about ten degrees in temperature in the mass is noticeable. Considerable difference of opinion exists as to the percentage of expansion which ordinarily occurs. Dr. Stewart J. Spence states that the average is about one per cent., while in the experiments I conducted, the average was about one-fourth of one per cent. Without doubt the difference noted can be partially accounted for by the difference in manipulation.

In the experiments alluded to, an effort was made to subject the material to the same treatment it ordinarily receives in the dental laboratory. No attempt was made to induce abnormal movement, which could easily have been brought about by long-continued and rapid stirring, and I am therefore of the opinion that my own estimate is more nearly correct. The fact remains, however, that all plasters expand, whether much or little, and that this movement, even under the most favorable conditions, results in enlarged and frequently warped molds.—J. H. PROTHERO, *Dental Register*.

OBITUARY.

DR. LUTHER W. SKIDMORE.

DIED, at Moline, Ill., February 23, 1906, DR. LUTHER W. SKIDMORE, in the forty-third year of his age.

Dr. Luther W. Skidmore was born in Morris, Ill., June 2, 1863. At nineteen years of age he entered the Dental Department of the Pennsylvania University, and was graduated in 1884. The following January, 1885, he commenced the practice of dentistry in Moline, Ill., and for twenty-one years has maintained a reputation and example which is well worthy of being followed by anyone, young or old, within or out of the dental profession.

Dr. Skidmore was closely identified with the Illinois State Dental Society, the First District Society of Illinois, the Tri-City Dental Society, and the Rock Island County Dental Society, and was actively and energetically engaged in every effort toward the success and welfare of each society above mentioned. He served as president of nearly all, and was recently elected vice-president of the Illinois State Dental Society.

Dr. Skidmore was genial of disposition, kindly of heart, and ever ready to help his fellow men, qualities which won for him a large circle of friends. He was a member of several secret organizations.

He is survived by his mother—Mrs. D. Hall Skidmore; his brothers—Dr. Wallace G. Skidmore now of Minneapolis, and Byron G. Skidmore of Moline, Ill., and his daughter Alice.

RESOLUTIONS OF REGRET.

Out of respect to the memory of Dr. Skidmore, the Rock Island County Dental Society adopted the following resolutions, February 27, 1906:

Whereas, The hand of Providence has removed from our midst our honored brother in the profession, Dr. L. W. Skidmore; and

Whereas, In his death we have lost one of our most active members, who until his death evinced a warm interest in the welfare of our

association; and who as a member of the various societies of the state gave freely of his time and energy for their betterment and advancement; therefore be it

RESOLVED, That we, the members of the Rock Island County Dental Society, desire to and do express to his family our sympathy and sorrow in their affliction, and our admiration for the professional and personal qualities of our member, who was our friend, ever ready to extend a helping hand to a brother: and be it

RESOLVED, That these resolutions be spread upon the records of our association, a copy be sent to the family of our departed brother, and others to the dental journals for publication.

W. T. MAGILL,
W. G. HAY,
H. G. TRENT,
Committee.

DR. SIDNEY L. GEER.

DIED, following a surgical operation at his home in the Geer block, Norwich, Conn., on Wednesday, April 18, 1906, DR. SIDNEY L. GEER, in the sixty-eighth year of his age.

Dr. Sidney L. Geer was one of the best known practitioners of dentistry in eastern Connecticut. He was born in Scotland, Conn., September 17, 1838, and was the son of Jephthah and Olive Starkweather Geer. He attended the public schools of his native town, and in 1855, when seventeen years of age, went to Norwich to learn the profession of dentistry under the preceptorship of Dr. E. K. Cook, who in 1858 went to South America, where he located and practiced and died. Dr. Geer succeeded Dr. Cook in the practice of dentistry, and has remained there ever since, having lived in Norwich for over half a century. Dr. Geer was an advertiser in the first issue of the *Norwich Bulletin*. He built up an extensive practice, owing to his professional skill and pleasing disposition. Dr. Geer, in 1877, erected a fine brick block on Broadway, where he spent his last years.

Dr. Geer was a staunch republican and for eight years was a member of the board of

water commissioners, being chairman of the board for four years. In the water department he was always deeply interested, and also in every public matter which came up in Norwich.

He was a man with the courage of his convictions and was held in the highest esteem by his many friends. He possessed a pleasant, jovial disposition, was kind-hearted and liberal, and will be greatly missed. He was a man whose opinion was sought on many subjects and his advice was sound and practical.

He married Harriet Perry, in Norwich, July 20, 1865, and she died March 15, 1898. Dr. Geer's only brother, Henry B. Geer, died April 18, 1900.

DR. JACOB LAFAYETTE WILLIAMS.

DIED, at his home, No. 4 Walnut st., Boston, Mass., May 15, 1906, JACOB LAFAYETTE WILLIAMS, M.D., in his eighty-third year.

Dr. Williams was born at Mansfield, Mass., March 16, 1824. He was the son of Jacob and Ada (Perry) Williams, and in his youth had lived for some years in the family of his uncle, Dr. William Perry, with whom he later studied medicine. After completing a literary course at Brown University, he matriculated in the medical school of Harvard University, from which institution he was graduated with the degree of M.D. in 1848. Later, he specialized in dentistry, and achieved marked distinction for his professional skill and ability to successfully fulfill the arduous duties of an extensive practice.

Dr. Williams was a philanthropist who gave freely of his means for the support of all worthy objects brought to his attention. Professionally, he displayed intense interest in all matters pertaining to his chosen specialty, holding active membership in the National Dental Association, the American Academy of Dental Science, the National Dental Association, the American Medical Association, the Massachusetts Medical Society, and

the Society for the Advancement of Oral Science.

DR. WILLIAM TELL LAROCHE.

DIED, at Harrington Park, New Jersey, February 8, 1906, WILLIAM TELL LAROCHE, D.D.S., in the eighty-third year of his age.

Dr. LaRoche was born at Frenchtown, N. J., July 30, 1822. He started upon the study of dentistry unassisted, and by studying at night acquired a good share of the dental knowledge available at that period. He started in practice in New York city in about 1840, opening an office in Bleeker st. Later on he studied in the New York College of Dentistry, receiving from that school the D.D.S. degree. He was a member of the First District Dental Society of the State of New York, of the Alumni Society of the New York College of Dentistry, and an ex-president of the Board of Trustees of his alma mater.

DR. JEROME PLUMMER TRIPP.

DIED, of pneumonia, at his home, 17 Lincoln st., New Bedford, Mass., January 8, 1907, JEROME PLUMMER TRIPP, D.D.S., in the thirty-eighth year of his age.

Dr. Tripp was born at Rochester, Mass., November 26, 1869, and entered upon the study of dentistry in January 1893, under the tutorship of Drs. E. V. McLeod and A. L. Shockley. He later on became a student at the Boston Dental College, receiving the D.D.S. degree in 1896. Dr. Tripp was a member of the Massachusetts Dental Society and of Psi Omega Dental Fraternity.

An estimable man, of high professional ideals, of unimpeachable moral character, of genial temperament, and self-sacrificing tendencies, the community in which he lived mourns the loss of one who completely fulfilled all the requisites of exemplary citizenship.

Dr. Tripp is survived by his widow and two children.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS:

April, May, and June, 1907.

APRIL.

CONNECTICUT STATE DENTAL ASSOCIATION. New London. Two days: April 16th and 17th.

FIFTH DISTRICT (NEW YORK) DENTAL SOCIETY. Syracuse. Two days: April 9th and 10th.

MONTANA STATE DENTAL SOCIETY. Helena. Two days: April 12th and 13th.

MAY.

ALABAMA DENTAL ASSOCIATION. Birmingham. Four days: May 14th to 17th.

ARKANSAS STATE DENTAL ASSOCIATION. Eureka Springs. Three days: May 29th to 31st.

EASTERN INDIANA DENTAL ASSOCIATION. Anderson. Two days: May 14th and 15th.

GEORGIA STATE DENTAL SOCIETY. Atlanta. Four days: May 7th to 10th.

ILLINOIS STATE DENTAL SOCIETY. Quincy. Four days: May 14th to 17th.

IOWA STATE DENTAL SOCIETY. Cedar Rapids. Three days: May 7th to 9th.

KENTUCKY STATE DENTAL ASSOCIATION. Louisville. Three days: May 20th to 22d.

LAKE ERIE DENTAL ASSOCIATION. Cambridge Springs. Three days: May 21st to 23d.

MISSISSIPPI DENTAL ASSOCIATION. Meridian. Three days: May 28th to 30th.

NEW YORK STATE DENTAL SOCIETY. Albany. Two days: May 10th and 11th.

OREGON STATE DENTAL ASSOCIATION. Portland. Three days: May 9th to 11th.

SOUTH DAKOTA STATE DENTAL SOCIETY. Sioux Falls. Three days: June 5th to 7th.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION. Los Angeles. Three days: May 6th to 8th.

SOUTHERN WISCONSIN DENTAL ASSOCIATION. Lancaster. Three days: May 21st to 23d.

VERMONT STATE DENTAL SOCIETY. Burlington. Three days: May 15th to 17th.

JUNE.

COLORADO STATE DENTAL SOCIETY. Colorado Springs. Three days: June 20th to 22d.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: June 11th to 13th.

MASSACHUSETTS DENTAL SOCIETY. Boston. Three days: June 5th to 7th.

NEW HAMPSHIRE DENTAL SOCIETY. Plymouth. Three days: June 25th to 27th.

SOUTH DAKOTA DENTAL SOCIETY. Sioux Falls. Three days: June 5th to 7th.

MINNESOTA BOARD OF EXAMINERS. Minneapolis. April 2d to 4th.

NEBRASKA BOARD OF EXAMINERS. Lincoln. May 29th to 31st.

NEW HAMPSHIRE BOARD OF REGISTRATION. Manchester. June 11th to 13th.

TEXAS BOARD OF EXAMINERS. San Antonio. June 10th.

WEST VIRGINIA BOARD OF EXAMINERS. Wheeling. June 12th to 14th.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

THE next meeting of the *Fédération Dentaire Internationale*, to be held at Amsterdam on August 8 and 9, 1907, promises to be one of exceptional interest, as a number of questions of great importance to the federation, as well as to the whole dental profession, must receive a thorough consideration at this time.

Our experience has brought out a number of points in the rules and regulations which require to be cleared up. The question of a pamphlet containing specific directions for the care of the teeth, presented in a form adapted to widest circulation among the poor, is also to receive its final settlement at Amsterdam.

Particular attention will be devoted to a matter which after a period of comparative quiet is again agitating the minds of dental teachers and practitioners, and which concerns the education which in future should be demanded of the dentist. The question whether the dentist should above all things be a full graduate in medicine, with a knowledge, more or less complete, of dentistry superadded, or should begin somewhat earlier to so shape his course as to best enable him to meet the demands which his profession and his patients make on him, is one which the F. D. I. has already pronounced upon in its session at Stockholm in August 1902. It cannot, however, be considered as having been definitely disposed of. It is, on the contrary, perhaps more acute at present than at any previous period in the history of our professional development.

The position of the F. D. I. having become more firmly established and its vote more authoritative, it is very desirable that its opinion should again be heard on this most important question, and every member should come prepared to give definite expression to his views.

Another point to be dealt with relates to the action of the committee of organization of the next international medical congress to be held in Budapest in 1909, in excluding from participation dentists who do not possess the medical degree. A consideration of

the right and duties of the F. D. I. in connection with the international dental congress to be held in Berlin in the same year will also take up some of the time.

These are a few of the matters which require special attention, and I sincerely hope that members will make every possible effort to be present. The steps taken toward the founding of an intellectual world-center at the Hague, if realized—and there seems to be every reason for trusting that such will be the case—will give an impulse to internationalism which will add greatly to the significance and importance of the F. D. I., and the hopes that it will be able to accomplish much in the interest of our profession and of humanity at large seem nearer fulfillment now than ever before.

W. D. MILLER, *President*.

[JAMESTOWN EXPOSITION, NORFOLK, VA.,
1907.]

JAMESTOWN DENTAL CON- VENTION,

TO BE HELD AT

Norfolk, Va., Sept. 10-12, 1907.

Committee of Organization.

BURTON LEE THORPE, St. Louis, Mo., *Chairman*.

H. WOOD CAMPBELL, Suffolk, Va., *Secretary*.

F. W. STIFF, Richmond, Va., *Treasurer*.

R. H. WALKER, Norfolk, Va.

THOS. P. HINMAN, Atlanta, Ga.

J. E. CHACE, Ocala, Fla.

CLARENCE J. GRIEVES, Baltimore, Md.

The Jamestown Dental Convention, to be held under the auspices of the Jamestown Exposition Company, the Southern Branch of the N. D. A., and the Virginia State Dental Association, will convene at Norfolk, Va., September 10 to 12, 1907. The Jamestown Exposition Company have appointed the above named gentlemen as a Committee on Organization, to elect officers in advance of the meeting, to appoint all committees, to finance the meeting, and to bring it to a successful termination.

The Committee on Organization have appointed Dr. Clarence J. Grievess, Baltimore, Md., general chairman of the Clinic Committee and Supervisor of Clinics.

A number of well-known men will assist him on the General Committee. State clinic chairmen have been selected from every state in the Union. The clinics are to be the principal feature of the convention, and it is expected to bring about the largest and most instructive dental clinics ever held. A surgical clinic will also be held under the supervision of Dr. L. M. Cowardin, Richmond, Va. The other members of this committee are J. Y. Crawford, Nashville, Tenn., and A. G. Friedrichs, New Orleans, La. Dr. F. W. Stiff, Richmond, Va., is general chairman of the Membership Committee.

Assistant state chairmen have been appointed from every state in the Union. Already membership fees are being sent in, and the promise is for the largest gathering of dentists ever held. Only five essays will be read at the convention, one by Prof. W. D. Miller, another by Prof. G. V. Black, and the other three by well-known southern dentists.

Several exhibits of much interest to the profession will be held under the auspices of the convention; among them the dental manufacture exhibit in charge of Dr. John W. Manning, chairman, Norfolk, Va.; a comparative anatomy exhibit, in charge of Dr. W. M. Bebb, chairman, Los Angeles, Cal., which exhibit will consist of three thousand comparative anatomy specimens, and also numerous other collections of interest; a dental historical exhibit, consisting of ancient instruments, operative and prosthetic work, books and photographs, under the chairmanship of Dr. Wm. H. Trueman, Philadelphia, Pa.; the orthodontia exhibit, showing a large collection of models, etc., under the chairmanship of Dr. H. E. Kelsey, Baltimore, Md. The U. S. Naval dental exhibit, showing 3000 charts of the mouths of midshipmen, will be under the chairmanship of Dr. Richard Grady, the U. S. dental surgeon of Annapolis, Md. The exhibit of the U. S. Army Dental Corps, under the chairmanship of Dr. John S. Marshall, San Francisco, Cal., will also show the equipment, method of keeping records, etc., used by the dental corps.

A full list of the various officers, who are to be elected in advance by the Committee on Organization at their next meeting in February 1907, and of the committees, will appear in due time in the various dental journals. The Committee of Organization is expected to

select officers in advance in order that the officers may be prepared for their duties before the actual meeting of the convention.

A cordial invitation is extended to all reputable members of the profession to become members of this convention, and to assist the Committee on Organization in bringing about one of the best, if not the best, dental meeting ever held.

The Exposition itself offers an excellent opportunity for the busy practitioner to take a delightful vacation, see the wonderful historical and naval and military exhibits at the Exposition, and also to participate in this meeting. The membership fee, which is \$5.00, should be sent to Dr. F. W. Stiff, treasurer, 600 East Grace st., Richmond, Va.

For further information address

H. W. CAMPBELL, Sec'y,
Suffolk, Va.

SOUTHERN BRANCH, N. D. A.

NOTICE TO MEMBERS.

I HAVE several copies of the N. D. A. Transactions for 1904-05, and will be glad to send one, as long as they last, to anyone entitled to a copy and who has not received one.

B. D. BRABSON,
Knoxville, Tenn.

NATIONAL DENTAL ASSOCIATION.

ANNOUNCEMENT OF CLINIC.

THE work of arranging the clinical operations, table clinics, etc., for the coming N. D. A. meeting, is progressing. I had hoped that I might at this time publish the names of the district and state chairmen, but that is impossible. The fearful floods and the great amount of snow which has fallen have prevented the usual mail facilities. It must be this, for the letters sent December 20, 1906, in many cases still remain unanswered.

Plans have been made, which if followed, should result in bringing to the meeting men from all the states in the Union and Canada.

As soon as possible each state will be provided with a local chairman, who will make every effort to obtain such an array of talent that the clinic of the National Dental Association—which is to be held at Minneapolis on July 31st and August 1st—may be the

best ever arranged for the consideration of the members.

The work of the clinic has been divided. W. N. Murray, Medical block, Minneapolis, has been appointed chairman of the Inlay Section. Dr. Murray is arranging special features for his department. Dr. W. R. Clack of Clear Lake, Iowa, the secretary of the Clinic Section, has the territory west of the Mississippi river entirely under his jurisdiction. I have the rest of the United States and Eastern Canada under my care.

The Executive Council has invited the members and friends of the G. V. Black Dental Club to operate on one of the days of the clinic. The invitation will be extended to them, and beyond a doubt it will be accepted.

The fact that I have been chosen chairman of the Clinic Section does not mean that the clinic is to be a "Black Club" clinic. It simply means this—that I hereby extend a most cordial invitation to all reputable dentists in the United States and Canada to come, meet with us, and if you have anything new to introduce in methods of filling teeth or some new appliance you wish to demonstrate at a table clinic, come to us and be welcome. Every chance will be given all to assist in making this a most memorable clinic. (I am not in position to invite to the clinic those who have patented instruments or methods to sell—their place is the exhibit room.)

I would like every man who has anything which he feels is of value to others, to know that if he will come and demonstrate it, there is room on the program and at the meeting for him.

I am depending upon the district and state chairman to assist me. One man may do much, but many men who are willing to work, and who do work, are able to do much more. I am bending every energy to making this clinic the best which the National has ever held. More no man is able to do.

The dental journals for July will contain the clinical program. Those who wish their names to appear as operators or table clinicians must have them in my hands by June 1st, as on July 1st the N. D. A. program goes to the printer.

E. K. WEDELSTAEDT, *Ch'man Clinic Section,*
New York Life bldg., St. Paul, Minn.

VOL. XLIX.—32

A PUBLIC DENTAL LIBRARY For Columbus, Ohio.

THE Trustees of the new Columbus Carnegie Library Building, a handsome structure costing \$250,000, have set apart a room 40 by 60 feet for the exclusive use of a Dental and Medical Library.

The local dentists have organized a Dental Library Association for the express purpose of bringing this matter to a successful issue, and the work thus far accomplished far exceeds our expectations. The Columbus dentists alone have donated \$500 in cash and a number of books and magazines.

To make this library complete in embracing all known works pertaining to our specialty and complete files of all the journals published, we desire the co-operation of every dentist in the state. Any old and rare works, copies of old journals, etc., will be gratefully received, inscribed with the name of the donor, and recorded to his credit in the library catalog. Please communicate with us concerning any literature you may have that you can donate to this cause, giving titles and authors of books; names and dates of journals, etc. In case of duplication they will be valuable for exchange with other libraries.

W. H. TODD, *Pres.*,
190 S. High st.
EDWARD C. MILLS, *Sec'y*,
10 Y. M. C. A. bldg.

FIRST FRENCH CONGRESS OF STOMATOLOGY.

A CONGRESS of stomatology, styled the First French Congress of Stomatology, will take place in Paris from August 1 to 5, 1907.

The Committee of Organization is as follows: Drs. Galippe and Redier, honorary presidents; Dr. Cruet, president; Drs. Claude Martin of Lyons, and J. Ferrier, vice-presidents; Dr. Chompret, general secretary; Dr. Girce, treasurer.

The Congress will be open to all French and foreign doctors of medicine who are interested in dental and oral science. Subscriptions and communications should be addressed to

DR. CHOMPRET, *General Sec'y*,
182 rue de Rivoli, Paris.

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

THE National Association of Dental Examiners will hold their twenty-fifth annual meeting in Minneapolis, Minn., beginning Friday, July 26th, and continuing through the 27th and 29th. A large attendance of delegates is earnestly requested.

Accommodations have been secured in the leading hotel of Minneapolis—The West Hotel. Rates will be as follows: Rooms without bath, \$1.00 per day for each occupant; with bath, \$2.00 per day for one person, and \$1.50 per day for each additional person in room. The hotel is run on the European plan. Any room in the hotel is capable of accommodating two people. All the rooms have telephone connection, and hot and cold water. Railroad rates will be given later.

The Committee on Colleges, Joint Conference Committee, Tabulation of Examining Boards' Reports, and the Committee for Promoting a System of Credits and Uniformity of Examinations will all give exceedingly interesting reports, valuable to all the members of the association.

CHAS. A. MEEKER, *Sec'y-Treasurer*,
29 Fulton st., Newark, N. J.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE forty-third annual convention of the Connecticut State Dental Association will be held at New London, Conn., Tuesday and Wednesday, April 16 and 17, 1907. The following essays will be presented:

Dr. F. B. Noyes, Chicago, "The Structure of Enamel with Reference to Cavity Preparation."

Dr. H. C. Ferris, Brooklyn, N. Y., "Antiseptic Sprays and Their Physiological Action."

Dr. G. M. Griswold, Hartford, Conn., "Burnished Fillings."

Dr. E. Whitford, Westerly, R. I., "Our Old Stand-by."

Dr. A. J. Flanagan, Springfield, Mass., "Comparisons are Odious."

Dr. F. S. Belyea, Brookline, Mass., "The Artistic Arrangement of Teeth."

E. S. ROSENBLUTH, *Sec'y*.

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

THE annual meeting of the National Association of Dental Faculties will be held in Minneapolis, Minn., commencing at 2 P.M., Friday, July 26, 1907.

The Executive Committee will meet at 10 A.M. the same day. The West Hotel has been selected as headquarters and place of meeting. Hotel rates as published in the notices of the meeting of the National Association of Dental Examiners will prevail.

H. B. TILESTON, *Ch'man Ex. Committee*,
B. HOLLY SMITH, *Sec'y Ex. Committee*,
1007 Madison ave., Baltimore, Md.

MONTANA STATE DENTAL SOCIETY.

A MEETING of the Montana State Dental Society will be held in Helena, April 12 and 13, 1907.

W. E. TREBISSE, *Sec'y*,
Helena, Mont.

FIFTH DISTRICT (N. Y.) DEN- TAL SOCIETY.

THE thirty-ninth annual meeting of the Fifth District Dental Society of the State of New York will be held at the Yates Hotel, Syracuse, N. Y., April 9 and 10, 1907.

C. A. SAYERS, *Rec. Sec'y*.

OREGON STATE DENTAL ASSOCIATION.

AT the last meeting of the Executive Committee of the Oregon State Dental Association, it was decided to hold the annual meeting in Portland, Ore., May 9, 10, and 11, 1907.

JEAN CLINE, *Sec'y-Treasurer*,
Portland, Ore.

SOUTHERN WISCONSIN DEN- TAL ASSOCIATION.

THE thirteenth annual meeting of the Southern Wisconsin Dental Association will be held at Lancaster, Wis., May 21, 22, and 23, 1907. All reputable practitioners are cordially invited.

C. W. COLLVER, *Sec'y*,
Clinton, Wis.

ARKANSAS STATE DENTAL ASSOCIATION.

THE Arkansas State Dental Association will hold its annual meeting at Eureka Springs, Ark., May 29, 30, and 31, 1907.

HENRY P. HOPKINS, *Sec'y-Treas.*,
Argenta, Ark.

EASTERN INDIANA DENTAL ASSOCIATION.

THE Eastern Indiana Dental Association will meet in Anderson, Ind., May 14 and 15, 1907. Good clinics, good papers. Everybody invited. Everybody who comes is a member.

C. W. ORLAND,
Anderson, Ind.

ILLINOIS STATE DENTAL SOCIETY.

THE forty-third annual meeting of the Illinois State Dental Society will be held at Quincy, on Tuesday, Wednesday, Thursday, and Friday, May 14, 15, 16, and 17, 1907.

ARTHUR D. BLACK, *Sec'y*,
31 Washington st., Chicago.

KENTUCKY STATE DENTAL ASSOCIATION.

THE next annual meeting of the Kentucky State Dental Association will convene at Louisville, Ky., May 20, 21, and 22, 1907. We anticipate a most interesting and profitable meeting. A cordial invitation is extended to the profession.

W. M. RANDALL, *Sec'y*,
Louisville, Ky.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

THE tenth annual session of the Southern California Dental Association will be held in Los Angeles, May 6, 7, and 8, 1907, at the same time that the Imperial Council of Mystic Shrine meets here, and all members of the dental profession contemplating visiting southern California at that time will confer a favor upon the association by notifying

CHAS. M. BENEBROOK, *Sec'y*,
455 S. Broadway, Los Angeles, Cal.

NEW YORK STATE DENTAL SOCIETY.

THE thirty-ninth annual meeting of the New York State Dental Society will be held at Hotel Ten Eyck, Albany, May 10 and 11, 1907, convening promptly at 10 o'clock on the morning of the first day, at which time the president desires to see every member present. A program of reports and essays of unusual interest will be presented, and on Saturday afternoon a large number of special chair and table clinics will be given. A cordial invitation is extended to all reputable practitioners to attend the sessions.

PROGRAM.

Dr. W. A. White, President's Address.

Dr. A. H. Peck, Chicago, "The Value of Association."

Dr. Clarence J. Grieves, Baltimore, "The Soldered Porcelain Facing Checked: Causes and Remedies." Illustrated.

Dr. Eugene Talbot, Chicago, "Acid Auto-intoxication and Systemic Diseases the Cause of Erosion and Abrasion."

Dr. L. C. F. Hugo, Washington, "Preparing Dental Papers."

Dr. G. V. I. Brown, Milwaukee, "Oral Surgical Lessons." Illustrated.

Dr. Chas. McManus, Hartford, "Pierre Fauchard." Illustrated.

Dr. Nelson T. Shields, New York city, "Treatment and Filling of Root-canals."

Dr. I. C. Curtis, Fulton, N. Y., "Fifty Years of Dental Science, with its Fads and Foibles."

Dr. S. L. Goldsmith, New York city, Report of the Correspondent.

Dr. E. Howard Babcock, Brooklyn, Report of the Committee on Practice.

Dr. Emanuel Muntz, Buffalo, Report of the Committee on Scientific Research: "Saliva Sulfocyanate Test."

There will be an interesting exhibit of dental appliances and supplies by the leading dealers in the country. For any information regarding exhibits, address Dr. J. L. Appleton, 89 Columbia ave., Albany, N. Y.

A railway rate of a fare and one-third, on the certificate plan, for those attending the meeting will be secured. Tickets at full fare for the going journey may be purchased within three days previous to and during the

first day of the meeting. Be sure, when purchasing ticket, to request a certificate. On arrival at the meeting, present the certificate, with twenty-five cents, to the secretary, Dr. C. S. Butler.

Tickets good returning not later than May 15th.

W. A. WHITE, *President*.
CHAS. S. BUTLER, *Sec'y*,
Buffalo, N. Y.

IOWA STATE DENTAL SOCIETY.

THE forty-fifth annual meeting of the Iowa State Dental Society will be held at Cedar Rapids, Iowa, May 7, 8, and 9, 1907. A good program is being arranged for. A cordial invitation is extended to the profession.

C. L. TOPLIFF, *Sec'y*.
Decorah, Ia.

MISSISSIPPI DENTAL ASSOCIATION.

THE fourteenth annual meeting of the Mississippi Dental Association will convene in the county court-house in Meridian, May 28, 29, and 30, 1907. All ethical practitioners of this and other states are cordially invited to attend. Reduced railroad rates and reduced hotel accommodations will be secured.

For full particulars, address

E. DOUGLAS HOOD, *Sec'y*,
Tupelo, Miss.

WASHINGTON UNIVERSITY DENTAL DEPARTMENT.

MEETING OF ALUMNI.

A MEETING of the Alumni Association of Washington University Dental Department (Missouri Dental College) will be held May 20, and 21, 1907, at the college building, 2645 Locust st., St. Louis, Mo.

A number of prominent essayists and clinicians have been secured, and an interesting and instructive program will be presented. Adequate space has been secured for the various manufacturers' exhibits; this will be a noteworthy feature of the meeting. All ethical practitioners are invited.

A. J. PROSSER, *Chairman*,
F. W. HORSTMANN,
CHAS. HERBERT.

GEORGIA STATE DENTAL SOCIETY.

THE next annual meeting of the Georgia State Dental Society will be held in Atlanta, May 7, 8, 9, and 10, 1907. All ethical practitioners are cordially invited to attend.

D. H. MCNEILL, *Cor. Sec'y*,
Athens, Ga.

ALABAMA DENTAL ASSOCIATION.

THE next annual meeting of the Alabama Dental Association will be held in Birmingham, Ala., May 14 to 17, 1907. Reduced rates on all railroads. All ethical dentists are invited to attend.

F. A. JOHNSTON, *Sec'y*,
Sheffield, Ala.

LAKE ERIE DENTAL ASSOCIATION.

THE forty-fourth annual meeting of the Lake Erie Dental Association will be held at Hotel Rider, Cambridge Springs, Pa., on May 21, 22, and 23, 1907.

Upon our program this year are men of exceptional merit, and we are pleased to invite all reputable dentists and their friends to this beautiful place for convention purposes.

V. H. MCALPIN, *Sec'y*,
Warren, Pa.

ST. LOUIS DENTAL COLLEGE.

ALUMNI CLINIC.

THE Alumni Association of the St. Louis Dental College (formerly Marion-Sims) wish to announce that their annual clinic will be held at the college building, Grand ave. and Caroline st., on Tuesday and Wednesday, May 7 and 8, 1907.

All ethical members of the profession are cordially invited to come and enjoy the festival of good things being prepared, and every member of the alumni is especially requested to show his allegiance to the association by his presence.

JOHN BERNARD O'BRIEN,
W. L. O'NEILL,
Committee on Publicity.

VERMONT STATE DENTAL SOCIETY.

THE thirty-first annual meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 15, 16, and 17, 1907.

The society has in the past held most successful meetings, and we have every reason to expect that this will surpass any previous one, as a very interesting program has been prepared by the committee, and will be mailed in due time. Vermont has the largest per cent. of membership in its state society of any state in New England, and we hope to see every dentist in the state who is eligible a member.

THOMAS MOUND, *Sec'y*,
Rutland, Vt.

INDIANA STATE DENTAL ASSOCIATION.

THE forty-ninth annual meeting of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, June 11, 12, and 13, 1907. The Executive Committee has arranged an unusually interesting program for this meeting. A cordial invitation is extended to the profession to be present.

CARL D. LUCAS, *Sec'y*,
Indianapolis, Ind.

TEXAS STATE DENTAL ASSOCIATION.

THE Texas State Dental Association will hold its meeting in the city of San Antonio, June 13, 14, and 15, 1907.

G. W. STAPLES, *Sec'y*.

SOUTH DAKOTA DENTAL SOCIETY.

THE twenty-fifth annual meeting of the South Dakota Dental Society will be held at Sioux Falls, June 5, 6, and 7, 1907.

A most interesting program has been arranged, and we want to see the largest attendance the society has ever had. A larger membership is desired, and every eligible dentist in the state should become a member. A special invitation is extended to South-eastern Minnesota and Northwestern Iowa dentists to attend.

FERDINAND BROWN, *Sec'y*,
Sioux Falls.

COLORADO STATE DENTAL SOCIETY.

THE annual meeting of the Colorado State Dental Society will be held at Colorado Springs, June 20, 21, and 22, 1907. A good program is being arranged and a profitable meeting is assured. An invitation to attend is extended to all ethical dentists, and special efforts will be put forth to make it pleasant for visitors from other states.

The undersigned would be pleased to hear from any who may plan to attend the meeting.

I. C. BROWNLIE, *Ch'm Exec. Com.*,
404 California bldg., Denver, Colo.

MASSACHUSETTS DENTAL SOCIETY.

THE forty-third annual meeting of the Massachusetts Dental Society will be held in the Mechanic Association bldg., Huntington ave., Boston, Mass., June 5, 6, and 7, 1907.

An excellent program has been arranged by the Executive Committee. It will consist of essays, reports of special committees, clinics, and a large exhibit of dental and medical supplies. Special committees will report on the following interesting subjects: Tuberculosis and other preventable diseases, dental education, dental supplies, dental medicine, dental research, and dental hospitals. Gentlemen practicing dentistry in the state of Massachusetts are invited to join the society.

CHARLES W. RODGERS, *Sec'y*,
165 Howard st., Dorchester, Mass.

NEW JERSEY STATE DENTAL SOCIETY.

THE thirty-seventh annual meeting of the New Jersey State Dental Society will be held in the Auditorium at Asbury Park, N. J., commencing 10 A.M. July 17th and continuing through the 18th and 19th. The headquarters will be at the Hotel Columbia, at the rates of \$3.50 and \$4.00 per day, and all reservations must be made before July 1st.

Prominent dentists have signified their intention of reading papers, and the clinics will all be of a new and novel nature. Clinic committee in charge of Charles H. Dilts,

Trenton, N. J.; exhibit committee in charge of Walter Woolsey, Elizabeth, N. J. Programs will be out June 15th.

Last year over eight hundred dentists registered in attendance. The Auditorium where the meeting is held is the largest and best adapted building on the Jersey coast. Cut off the week of July 15th, and be with us.

CHARLES A. MEEKER, *Sec'y*,
29 Fulton st., Newark, N. J.

TENNESSEE STATE DENTAL ASSOCIATION.

THE annual meeting of the Tennessee State Dental Association will be held at Knoxville, Tenn., July 9 and 10, 1907. A splendid program is being arranged by the Executive Committee, and a most cordial welcome is extended to all.

R. J. MCGAVOCK, *Sec'y*,
Columbia, Tenn.

CHICAGO ODONTOGRAPHIC SOCIETY.

AT the annual meeting of the Chicago Odontographic Society the following officers were elected for the ensuing year: F. E. Roach, president; F. W. Gethro, vice-president; F. H. Zinn, secretary; G. W. Dittmar, treasurer; J. H. Woolley, librarian. Board of Directors—H. A. Drake. Board of Censors—F. B. Noyes, J. E. Hinkins, and C. E. Meerhoff.

FRANK H. ZINN, *Sec'y*,
100 State st., Chicago.

NEW YORK ODONTOLOGICAL SOCIETY.

THE annual meeting of the New York Odontological Society was held at the New York Academy of Medicine, 17 West Forty-third street, New York city, on December 18, 1906, with the president, Dr. F. T. Van Woert, in the chair.

The officers elected for 1907 were as follows: W. J. Turner, president; W. D. Tracy, vice-president; W. B. Dills, recording secretary; J. G. Fulton, corresponding secretary; F. C. Walker, treasurer; W. W. Walker, curator; W. B. Dunning, editor. Executive Committee—Ellison Hillyer (chairman), B. C. Nash, R. Ottolengui. Clinic Committee—R. M. Sanger (chairman), H. W. Gillett, J. W. Taylor.

WM. B. DUNNING, *Editor*.

NEW HAMPSHIRE DENTAL SOCIETY.

THE annual meeting of the New Hampshire Dental Society will be held at Plymouth, N. H., June 25, 26, and 27, 1907, beginning on the evening of the 25th. All members of the profession are cordially invited to be present.

FRED F. FISHER, *Sec'y*.

LOS ANGELES ASSOCIATION OF DENTAL ALUMNI.

AT a regular meeting of the Los Angeles Association of Dental Alumni the following officers were elected: Wm. Bebb, president; Genette F. Harbour, vice-president; W. W. Homan, secretary; Chas. E. Rice, treasurer. Program Committee—Jas. D. McCoy, J. F. Curran, and Horace E. Brown. Membership Committee—D. S. Gillespie, D. D. Cave, and H. Gale Atwater. Illegal Practitioners' Committee—J. F. Cook, Bert Boyd, and J. W. Neblett.

W. W. HOMAN, *Sec'y*.

ARMY DENTAL CORPS.

THE following changes in the stations and duties of dental surgeons are ordered: Dental Surg. Rex H. Rhoades from duty at Fort Sheridan to Columbus Barracks, Ohio, for duty, relieving Dental Surg. S. Davis Boak. Dental Surg. Boak will take the first available transport for Cuba. Dental Surg. John A. McAlister from duty at the Presidio of Monterey, Cal., to Fort Sheridan, Ill. (Dec. 28, W. D.)

Leave for seven days is granted Dental Surg. John A. McAlister. (Jan. 10, W. D.)

Dental Surgs. Ord M. Sorber and Edwin P. Tignor from duty in the Philippines Division, and will proceed on the transport to sail from Manila about April 15, 1907, to San Francisco, Cal., for further orders. (Feb. 5, W. D.)

Dental Surg. Edwin P. Tignor is relieved from duty in the Philippines Division, to take effect April 1, 1907, and is authorized to avail himself of the leave granted. (Feb. 9, W. D.)

Dental Surg. George E. Stallman, having reported at San Francisco, Cal., will proceed to Fort Sam Houston, Texas, for duty, relieving Dental Surg. Frank P. Stone, who will proceed to his home, Macon, Mo., for annulment of contract. (Feb. 15, W. D.)

ARIZONA BOARD OF DENTAL EXAMINERS.

THE Board of Dental Examiners of Arizona will meet at Phoenix, April 8, 9, and 10, 1907, for the purpose of holding examinations. The fee, twenty-five dollars (\$25.00), should be in the hands of the secretary twenty days before date of meeting. For further information, address

W. P. SIMS, *Sec'y*,
Box 58, Bisbee, Ariz.

MINNESOTA BOARD OF DENTAL EXAMINERS.

THE Minnesota State Board of Dental Examiners will hold its next regular meeting at Minneapolis, in the Medical Building of the State University, on April 2, 3, and 4, 1907. All applications must be in the secretary's hands by 11 o'clock of April 2nd. Candidates will be furnished all necessary blanks and such other information as is necessary, upon application to

GEO. S. TODD, *Sec'y*,
Lake City, Minn.

MARYLAND BOARD OF DENTAL EXAMINERS.

THE regular semi-annual meeting of the Maryland State Board of Dental Examiners for the examination of candidates for certificates will be held May 22 and 23, 1907, at the Baltimore College of Dental Surgery, Baltimore, at 9 A.M. Application blanks and full information will be furnished by

F. F. DREW, *Sec'y*,
701 N. Howard st., Baltimore, Md.

ALABAMA BOARD OF DENTAL EXAMINERS.

THE Board of Dental Examiners for the State of Alabama will meet in Birmingham, Ala., on the Monday before the second Tuesday in May 1907. In addition to the regular written examination the following requirements will be added: Each applicant must fill at least two teeth—approximal cavities—one with gold, the other with alloy, work to be done under the immediate supervision of the board. Board to determine or pass on suitable selections of cavities. Board will try to furnish subjects, but failing to do so,

applicants for license must find or bring their own subjects, also instruments and material.

Each applicant must take or have taken an impression of his own mouth. Make a plaster cast of the same, cut from the cast the six anterior teeth, and make a bridge for same with porcelain facings. Cast can be made and facings fitted before the examination, but the backings must be put on and the facings arranged, also invested and soldered, under the supervision of the board, hard solder being required.

THOS. P. WHITBY, *Sec'y*.

ARKANSAS BOARD OF DENTAL EXAMINERS.

THE Arkansas State Board of Dental Examiners will hold examinations at Eureka Springs, Ark., May 27 and 28, 1907.

A. T. McMILLIN, *Sec'y*,
Little Rock, Ark.

NEBRASKA BOARD OF DENTAL EXAMINERS.

THE next meeting of the Nebraska Board of Dental Examiners will be held at the State-house, in Lincoln, Nebr., May 29, 30, and 31, 1907. All applicants for examination must have their applications in the hands of the secretary five days before this date.

For further information address.

C. F. LADD, *Sec'y*.
1241 O. st., Lincoln, Nebr.

CONNECTICUT DENTAL COMMISSIONERS.

THE Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford on Thursday, Friday, and Saturday, June 13, 14, and 15, 1907, to examine applicants for license to practice dentistry, and for the transaction of any other business proper to come before said meeting.

Applicants should apply to the recorder for proper blanks and rules for conducting the examination. Application blanks must be filled in and sworn to, and with fee, filed with the recorder on or before June 6, 1907. By order of Commission.

GILBERT M. GRISWOLD, *Recorder*,
783 Main st., Hartford, Conn.

INDIANA BOARD OF DENTAL EXAMINERS.

THE next regular meeting of the Indiana State Board of Dental Examiners will be held in the Capitol at Indianapolis, June 11, 12, and 13, 1907. Applications must be in the hands of the secretary at least five days before the above date. Address

F. R. HENSHAW, *Sec'y*,
Middletown, Indiana.

NEW HAMPSHIRE BOARD OF REGISTRATION.

THE next meeting of the New Hampshire Board of Registration in Dentistry for examination of applicants for registration will be held in Manchester, N. H., June 11 to 13, 1907.

A. J. SAWYER, *Sec'y*.

WEST VIRGINIA BOARD OF DENTAL EXAMINERS.

THE West Virginia State Board of Dental Examiners will hold their next meeting for the examination of candidates at Wheeling, W. Va., June 12, 13, and 14, 1907. For further information address

H. M. VAN VOORHIS, *Sec'y*,
Morgantown, W. Va.

TEXAS BOARD OF DENTAL EXAMINERS.

THE Texas State Board of Dental Examiners will hold their next regular meeting at San Antonio, Texas, June 10, 1907, at 10 A.M. For further information address

C. C. WEAVER, *Sec'y*,
Hillsboro, Texas.

CALIFORNIA BOARD OF DENTAL EXAMINERS.

THE next examination of the California Board of Dental Examiners will be held in Los Angeles beginning June 10, and in San Francisco beginning June 17, 1907.

C. A. HERRICK, *Sec'y*,
Jackson, Cal.

IOWA BOARD OF DENTAL EXAMINERS.

THE Iowa State Board of Dental Examiners will hold its next meeting for examination at Iowa City, June 6, 7, 8, 10, and 11, 1907. Applicant must hold a diploma from a college on the accredited list of the National Association of Dental Examiners, and must state where he attended first, second, and third year of college. Address

E. D. BROWER, *Sec'y*,
Le Mars, Iowa.

ORIGINAL COMMUNICATIONS.

THE PRESENT STATUS OF THE PORCELAIN INLAY.

By J. Q. BYRAM, D.D.S., Indianapolis, Ind.

(Read before Section I of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

THERE are periods in the history of the dental profession when its thought seems to be turned largely to one subject. We have just passed through the porcelain era, and many of the leading journals have been devoting a large amount of space to porcelain. We now have another outburst of enthusiasm on inlays, but this time the enthusiasm is for the gold instead of the porcelain inlay. After the gold inlay has run its course we shall be so familiar with the inlay principle of filling teeth that no progressive dentist should plead ignorance of the subject.

While a great deal has been written on porcelain, many of the writers, through a fit of enthusiasm, have made statements which have caused disappointment to those attempting to follow their teachings. It is probable that those

gentlemen who advocated porcelain as a filling material for all cavities, and who suggested that the gold and amalgam pluggers be discarded, to be used no more but to be kept only as relics of barbarism, are finding some use for these instruments today—for we have learned that porcelain should take its place with other filling materials, and not entirely displace them.

NEED OF THOROUGH KNOWLEDGE OF PRINCIPLES AND MASTERY OF TECHNIQUE.

Although many of the journals have been filled with articles on porcelain, it is surprising that such a large number of dentists have no knowledge of the inlay principle of filling teeth. And many are discouraging the use of porcelain because they are not familiar with its good quali-

ties. They may have seen a few failures, and because of these failures and their own ignorance, they are condemning it. Such dentists remind one of the laity who condemn modern surgery because they always learn of failures, but never of the many successful operations. There are others who, through inexperience and lack of knowledge of the principles of porcelain work, have made failures—they also are condemning it; for too many dentists have bought porcelain outfits and attempted the construction of porcelain inlays with but little conception of that which they were attempting.

The construction of porcelain inlays requires precision in each step of the operation. The best work can be accomplished only with a thorough knowledge of the principles of inlay work and the properties of porcelain, with mastery of technique, on the part of the operator.

Porcelain inlays have passed the experimental stage, and their use as an esthetic filling must be more universally recognized. The dentist who fails to master the technique of constructing porcelain inlays will be compelled to refer many of his patients to a specialist in this branch of dental art, for porcelain is the material that should be used to fill most cavities in incisors and canines.

As the size of cavities in vital incisors and canines increases, just in that ratio does the indication for porcelain inlays increase; for if a gold filling is conspicuous at the gingival margin of an incisor or canine, an approximo-incisal filling is conspicuous to a much greater degree. While there is a limit to the size of an inlay that may be successfully inserted in an approximo-incisal cavity, there are nevertheless too many crowns adjusted on anterior teeth. The ease with which a crown may be adjusted frequently causes operators to overlook the good qualities of porcelain inlays in many large cavities.

Porcelain makes a desirable filling for those approximo-occlusal cavities where the cavity extends too far beneath the gingival margin and involves a large portion of the occlusal surface. In those cases where it is impracticable to burnish

a matrix in the cavity, an impression may be swaged of gold 3-1000 of an inch or platinum 1-500 of an inch. If a heavy material is used for the matrix, there will be less danger of warpage during the process of fusing. The matrix, however, should become a part of the inlay. It should be trimmed close to the margin of the cavity after the final fusing, and after the inlay has been set, the matrix should be finished to the margins of the cavity at a subsequent sitting. This insures a better-fitting inlay, and one the margins of which are less liable to fracture. There is also less liability of the cement being washed away to any marked degree, for the matrix protects the cement in such a manner that a new wash-line does not form at those points where the porcelain may fracture at the margins.

While porcelain has the advantage over gold of giving a filling that more nearly harmonizes with the natural teeth, and one that is a non-conductor of thermal and electrical changes, it has still another advantage which should appeal to all conscientious operators, in that imperfect fillings are easily dislodged. A large number of faulty gold fillings which do not preserve the teeth are retained by deep grooves, so that it is almost impossible to dislodge them, thereby deceiving the patient, and many times the dentist. If the porcelain filling is faulty it is dislodged, and the patient knows immediately that the services of a dentist are required.

CAVITY PREPARATION.

It is essential that beginners should understand cavity preparation for inlay work. It is not uncommon for dentists to construct inlays for patients before they have studied the principles of cavity formation. It is not difficult to change the method of cavity formation, even though one has been preparing cavities for gold and amalgam for a long time, if the principles of retention for the different fillings are thoroughly understood.

The preparation of many cavities requires the sacrifice of sound tooth-struc-

ture in order to secure the necessary retentive resistance, to prevent frail margins of porcelain, and to obtain proper color. The writer has found in many instances that more sound tooth-structure is involved in the preparation of the cavity for porcelain inlay than would be involved in preparing the cavity for gold. Most porcelain workers are agreed that the cavities should be so prepared that the inlay receives as much retentive resistance as it is possible to give it. Absolute angles, both on the margins and in the cavity, are to be avoided. The cavities should be so prepared that all frail enamel is removed. It should be borne in mind that porcelain is a friable material; this fact is often overlooked, for too often we are careless in our cavity preparation; weak margins of porcelain are formed, which cause the filling to be imperfect, and all the blame is attributed to the material used and not to the method applied.

MATRICES—MATERIAL AND MANIPULATION.

The selection of material for matrices is partially dependent upon the kind of porcelain to be used and the personal equation of the operator. The writer uses gold for the construction of some matrices for low-fusing porcelain, but he believes platinum to be preferable in most cases. The elasticity of the platinum tends to prevent the distortion of the matrices in the withdrawal from many cavities, and because of the pliability of gold, the matrix will not always retain its original shape in the withdrawal.

The technique of burnishing a matrix is dependent upon the material. If thin gold is used, it should be worked to place with cotton or spunk, and very little burnishing with steel instruments should be done. If platinous gold or platinum is used, most of the burnishing may be done with steel instruments. A piece of foil, large enough to cover the cavity and to be held in position with the thumb and first finger, should be placed over the cavity. Use a ball burnisher as large as the cavity will permit, and work the ma-

trix into the seat of the cavity. After the matrix has been roughly burnished with the large ball burnisher, select a smaller one, and continue the work. Then place a small amount of hard wax or camphor in the matrix and swage it into the cavity. With a piece of tape or rubber dam, turn the matrix over the margin of the cavity. Remove the matrix and trim off the surplus foil, leaving enough material to cover the tooth and to give its contour. Anneal the platinum in the furnace, re-insert the matrix, and re-swage it by filling with camphor or hard wax; then swage it again with tape. If care be taken to conform the metal to the tooth before the final swaging is attempted, an accurately fitting matrix will be formed.

CARRYING THE MENTAL IMPRESSION OF TOOTH-FORM.

Cavity preparation may be thoroughly understood, the technique of matrix formation may be perfected, but until one can carry tooth-form in the mind's eye, one cannot construct inlays in the most artistic manner. Many operators can insert gold and amalgam fillings in such a manner that the lost tooth-structure is replaced with proper contour, but when they attempt to fill a matrix with porcelain the eye and hand do not work in unison, which results in an ill-contoured filling. One requisite of a skilful porcelain worker is the faculty of looking at a matrix and carrying the form of the lost portion of the tooth in the eye. To those who are unable to create a proper mental impression of the tooth-form, I would suggest a thorough course in tooth-carving as being of great assistance. Form cubes or rods of porcelain by mixing the porcelain to a creamy paste with water, and pouring into a matrix made of blotting paper. Then, with proper carving instruments, carve a tooth from the block of porcelain. Another requisite of a skilful porcelain worker is dexterity in handling the matrix and the instruments. Many operators handle matrices as though it were impossible to change their shape. Until one has become skilful in manipulating the matrix after it has been

properly formed, one may expect ill-fitting inlays. The matrix should be so protected and the fingers so guarded that all carving may be done in the matrix without distorting it.

Every porcelain worker is asked, what porcelain do you use? To such questions the writer usually replies by stating that he uses any of them. It makes little difference which porcelain one uses—but one should learn to use porcelain. The difficulty with many beginners is their unwillingness to devote the time to the experimental work which is required to obtain a thorough knowledge of the properties of porcelain. The general principles of manipulating all porcelains are the same. They may be mixed with alcohol, but this destroys their power to be molded and carved. Likewise all porcelains may be mixed with water, and this method insures the possibility of molding and carving.

COMPOSITION OF PORCELAIN.

In order to understand better the properties of porcelain it is necessary to consider the ingredients of which it is composed. Such a consideration shows porcelain to be made up of three classes of substances: (1) Three basal ingredients—silica the oxid of silicon, kaolin the silicate of aluminum, and feldspar the double silicate of aluminum and potassium—which are very refractory substances; (2) fusible substances known as fluxes, which fuse at a lower temperature, and which by combining with the basal ingredients increase the fusibility of these refractory substances, and (3) metals or their oxids, which are used as pigments, and which by combining with the porcelain under intense heat produce the various colors.

Silica and kaolin when heated separately withstand intense heat without undergoing any perceptible change. Feldspar undergoes liquefaction when subjected to a high degree of heat. When feldspar is added to silica and kaolin, the mass undergoes a chemical change which under intense heat causes it to vitrify. The materials commonly used as fluxes

to increase the fusibility of porcelain are sodium and potassium carbonate, or some material containing some other salts of sodium or potassium. When any of these materials are added to the basal ingredients, the fusibility of the mass is increased in ratio to the amount of flux added.

It was my good fortune to carry on a line of experiments on the fusing of different porcelains. After making over three thousand experiments, the following deductions were made:

(1) Porcelain has no definite fusing-point.

(2) By prolonging the time of exposure to heat, a thoroughly fused porcelain may be obtained at a comparatively low temperature.

(3) That porcelain fused at a low temperature for a long time will maintain its characteristic color.

(4) That low-fusing porcelains may be made of high-fusing porcelains by repeated fusing and grindings, but the properties are changed.

(5) If a piece of porcelain be thoroughly fused, then heated repeatedly to the maximum fusing-point, it becomes over-fused.

(6) That porcelains containing a large percentage of flux are more easily affected by bubbles than those that are more nearly composed of the basal ingredients, and that they should be heated more slowly.

Although all porcelains have properties in common, there are, however, certain properties that characterize each manufacturer's product. It is important that these characteristic properties be thoroughly understood in order to obtain the best results.

COLOR.

The power to obtain proper colors in the construction of inlays is a gift that cannot be easily imparted to others. This faculty can be acquired by a thorough knowledge of the principles of color formation and an eye trained to detect the delicate shading of colors in both the natural teeth and in porcelain.

One of the prevalent theories of color formation from pigments, known to artists and colorists, treats red, yellow, and blue as primary colors. According to this theory the many colors used by artists and colorists are produced from these three. When two of the primary colors are combined secondary colors are produced. Red and yellow, for instance, give orange; red and blue give violet, and blue and yellow give green. The excessive predominance of one color over another yields the hue to that color.

By combining the three primary colors so that complete absorption of light takes place, black is formed. The colors produced by the combination of the three primaries are termed tertiary colors. The third primary color, however, does not produce a new hue, but merely saddens the other two by forming a certain amount of gray or black in the combination. They are often called the dulled or broken tones of the primaries and secondaries.

Colors have three qualities, known as hue, purity, and luminosity. The excessive predominance of one color over another yields the hue to that color, and the greater the predominance the stronger will be the hue, *e.g.* when blue and yellow are mixed green is produced; if yellow predominates, the green will have a yellowish hue. The purity of a color is its lack of mixture of white or black or of any color. These admixtures not only weaken the color, but also change its character. This can be shown by adding a white porcelain to a yellow—the yellow is not only diluted, but tends to take a hue. The luminosity of a color is measured by the amount of light reflected to the eye, and is therefore independent of hue or purity. The most luminous color is yellow, while the least luminous is violet; and between these extremes are all the intermediate degrees of brightness. Those teeth wherein yellow and blue predominate appear more translucent because they reflect or transmit the rays; while those in which gray and brown predominate have a somewhat dull appearance, because their power of reflection and transmission of light is not so great,

for more of the rays are absorbed on the surface.

In order to become familiar with some of the phenomena of color formation, and to train the eye to detect the hues of colors, the writer finds it both pleasant and profitable to experiment with water- and oil-colors and porcelain. An outfit of water- or oil-colors containing the three primary colors is used. The secondary and tertiary colors with their various hues are produced.

Every porcelain worker should have the colors in porcelain that approximate the three primary colors, and study the formation of colors as applied to porcelain art. While it is impossible to procure pure red, yellow, and blue porcelains, it is possible, however, to obtain colors which when mixed in varying proportions will show the color formation in porcelain. I have found a special red and blue porcelain manufactured by The S. S. White Dental Mfg. Co., and a yellow by Mr. Robert Brewster, to meet the requirements for this work best of any of the porcelains in my possession.

CEMENT IN RELATION TO COLOR.

That the cement is a factor in the inlay problem is shown by the variation of color so often noticeable when the inlay is set. The inlay may be a good match when the incidence of light is at such an angle as will permit its transmission. But when the angle of incidence is changed, the color of the inlay may change. This phenomenon is caused by the cement—which is an opaque body—excluding the light from the dentin, absorbing certain rays, and reflecting others. And it is the reflected rays that change the color of the inlays.

For small inlays constructed of a monochromatic porcelain, a cement which is of the same color as the porcelain but of a lighter hue is best; for the rays that are transmitted through the porcelain are not absorbed by the cement, but reflected to the surface, with practically no change of color other than that due to intensification. I believe a pure white cement would be the best for set-

ting large approximal and all approximo-incisal inlays constructed of multi-colored porcelain, because white bodies do not absorb light, but reflect it. The same rays that are transmitted to the cement would then be reflected to the surface.

THE FUSING.

The color of the inlay is many times affected by over-fusing the porcelain. It is a fact that over-fused porcelain becomes lighter, and tends to take a glass-like appearance. If porcelain remains in contact with the maximum heat long enough, or if it is brought to the maximum-fusing heat by repeated fusing, it tends to form a glass-like mass. All the hues of a color, from the normal to a light one, may be made from the same porcelain by increasing the heat above its maximum fusing-point—but this is done at the sacrifice of its strength. In applying the enamels over the foundation, each layer should be fused only to a

high biscuit, heating the enamels to the point of glazing only at the final fusing. This prevents over-fusing the first layers.

I wish to condemn the method of fusing porcelain at its maximum temperature for a short time. It makes the porcelain more brittle, and causes the formation of minute bubbles throughout the mass. I also wish to protest against placing the porcelain in an intensely hot furnace, for it causes a crust to be formed on the surface, which prevents the escape of gas. This gas will seek the point of least resistance, which will be along the margin, and result in the formation of bubbles along the margin of the inlay.

If porcelain art is to maintain the high place in the dental art that its advocates are claiming for it, it must be treated as an art. And those who practice this art should acquire a thorough knowledge of the subject, in order that this knowledge may be placed in proper action.

REFLECTED SHADOWS ACCOMPANYING PORCELAIN FILLINGS.

By C. N. THOMPSON, D.D.S., Chicago, Ill.

(Read before Section I of the National Dental Association, Atlanta, Ga., September 18, 1906.)

IN restoring the lost parts of teeth with porcelain inlays, an exact match in appearance is probably considered the most difficult part of the operation, the success of which depends upon the exactness with which we produce the natural conditions. But depending as we do upon materials that differ in physical properties to the extent that porcelain and cement do from the natural tooth, we are compelled to make use of certain artifices intended to offset the shade that falls as a result of the unnatural reflection, refraction, absorption, and transmission of light by these materials.

Color, of course, is a factor of great importance, and in itself would constitute an ample topic for an entire paper; but when we remember that it is quite impossible to invisibly repair a broken porcelain tooth by means of cement—in fact, almost impossible to even replace the fragment in any way so that the fracture will be invisible—it would seem that color is not the only factor in the final appearance of finished porcelain fillings. The fragments being absolutely exact in color, translucence, form, and thickness, and the cement being of a good color, it is evident that aside from color there are

other phases of the phenomena of light which affect the finished inlay detrimentally, unless forestalled. The only way in which the fragment of a broken tooth can be replaced—concealing the fracture—is to moisten both with some liquid of the same reflective index as the tooth, which in absolutely filling the space, cancels the reflective surfaces of the fracture, both internally and externally, thus permitting the light to proceed as it did before the break occurred.

THE CEMENT PROBLEM IN RELATION TO COLOR.

Water answers admirably, but unfortunately it, like all other translucent substances of which we know, is of no practical value as a cement, so we are obliged to return to zinc oxyphosphate and its gloom, because it is *adhesive*. It may not be out of place to mention that although Ascher's enamel cement has practically no adhesive properties, and is consequently of no value in retaining inlays, its power of transmitting and reflecting light is so nearly equal to that of the natural tooth-enamel that certain shades of it interfere very little with the free passage of light, and it therefore comes very near being ideal in appearance. It is unfortunate that the good qualities of the cements mentioned cannot be incorporated into one—for a cement of the proper color, translucence, adhesiveness, and strength to fill all requirements, would mark the beginning of the end of the inlay question.

DIFFERENCE BETWEEN THE NATURAL TOOTH AND PORCELAIN IN REACTION TO LIGHT.

A study of the normal tooth reveals the fact that its exact reproduction is impossible, yet to restore tooth-structure in appearance with porcelain without due consideration for the details of the make-up of the normal tooth is a mistake, for an examination of a cross section of the natural tooth reveals the enamel nearly transparent and the dentin nearly opaque. Compare this with a cross section of a

porcelain tooth, and it is not hard to discover the reasons for some of our difficulties, as well as to know that there must be method in our efforts if we would secure results.

Dentin is so nearly opaque that it transmits light but feebly. Its opacity seems to be due, as much as to anything else, to the condition of its external surface, which is without glaze—under the magnifier it seems rough, like fine sand-paper. The external surface stops the light as do crushed transparent substances generally—as for instance common salt—for the reason that the rays of light are so often reflected among the particles on the surface that they are scattered into a multitude of crossed reflections that appear white, and therefore cannot enter. Thus it follows that whatever surface will not admit light will also refuse to allow a reflected shade to pass; consequently if the dentin can be restored with a very high-fusing porcelain that becomes densest before it glazes, that presents a vitreous surface resembling sand-paper, and of the color of dentin, we have produced a foundation for the filling that will not absorb sufficient light to cause a shadow, and which, if not glazed by a subsequent baking, will still retain the power to arrest transmitted light, no matter how the colors and enamel are laid on afterward.

The only phase of color I shall mention is that of red. A pulpless tooth usually assumes a grayish aspect, probably due to the oxidation of the contents of the tubuli of the dentin, whereas there is something in a healthy tooth that gives it a lifelike appearance. We all know that the dentin immediately covering the pulp is pink, and if it be a fact from any cause that there is a red or pink tinge to the dentin close to and surrounding the pulp of a vital tooth, may it not be that the color of the normal dentin, if analyzed, would reveal red? Following this thought, it has been the custom of the writer to make use of red in deep cavities, laying a little of it on the matrix beneath the foundation body in the vicinity of the pulp, and the result produced warrants the supposition that red

is present in vital teeth, and is necessary for the production of a lifelike filling.

Let us study the normal tooth filled with porcelain as it is seen in the mouth under normal conditions.

First, it is covered with moisture, which partly veils small mechanical defects, modifies the superficial, structural, and physical differences of the filling and tooth, fills the interspaces of the cement at the surface, and reflects a portion of the white light.

Next, through it we see the convex surfaces of the tooth and filling where another portion of the white light is reflected, and where reflections from nearby objects begin to appear. The tooth-enamel is as though polished, differing from the glaze of the porcelain. However all teeth are not alike in this respect, even those in the same mouth may differ. But seldom do we see natural tooth-enamel having as high a finish as well-glazed porcelain, and consequently it improves most porcelain fillings to polish that portion next to the labial cavity margin after it is set because it makes the surfaces more nearly alike. Comparing porcelain enamel with the natural structure, we find that it is not difficult to produce a substitute that resembles it in a general way—until its reflective and refractive powers are considered. Its translucence is very much the same as that of natural enamel, but as it is only a fused translucent crystal covering the inner parts of the filling, it becomes an elliptical cavo-convex lens, with all the abortive phenomena which accompany such instruments. The natural enamel with its radiative arrangement of enamel rods, whose refractive and reflective indices vary in accordance with their various positions, produces an entirely different instrument, for at the median line of the teeth the enamel rods point nearly toward the eye—those on the same perpendicular plane, while those on the sides are at right angles to the long axis of the tooth, which must produce a reversal of the reflecting index of each rod and consequently of the portion of the tooth which they occupy. This in the writer's opinion explains why an approximal gold

filling appears not to darken its approximating neighbor, if it be a sound one, to the extent that it would if filled with porcelain, because natural enamel does not accept impressions as does the porcelain enamel, on account of the repeated reflections among the rods; also explains why the appearance of most approximal fillings are improved by a very thin layer of opaque white at and on a line with the contact point, or a trifle more to the labial on the approximal exterior, which prevents the passage of the reflected shade.

OTHER OPTICAL PRINCIPLES INVOLVED.

As a consequence of the rectilinear motion of light, opaque bodies cast shadows, which fall as a result of some obstruction to the free passage of light, and their location, extent, and intensity are dependent upon the extent to which the light-rays are transmitted, reflected, refracted, or absorbed by the obstacle.

A shadow is partial darkness caused by the intervention of something between the space contemplated and the source of light. Reflected shade is that phase of the phenomena of light that affects porcelain inlays following final insertion.

All illuminated bodies scatter or reflect light, and are distinguished from each other by the kind and amount of light they send to us, their power of selective absorption and surface reflection determining the color. If the source of light be a point, as in the electric arc light, the shadow is sharply defined; if, on the other hand, it comes from a luminous surface, as the sun, the edges of the shadow are fringed and imperfect, due to the angular magnitude of the sun. For example the shadows of minute objects disappear almost immediately in sunlight, whereas the same objects in the arc electric light cast a well-defined shadow for a considerable distance if thrown upon a screen. This explains why porcelain fillings are more conspicuous in artificial light than in sunlight, the shadows thrown appearing more definite.

When light passes from one optical me-

dium to another, a portion of it is always turned back, *i.e.* reflected. This partly explains why a highly glazed filling that does not appear correct may be improved by grinding or polishing. A slight roughening of its surface causes less direct exterior reflection, and although it thus renders the surface slightly more opaque, it renders the deeper coloring more prominent, because light is reflected regularly and more fully by a glazed surface.

One of the fundamental laws of optics is that the angle of incidence in light-rays is equal to the angle of reflection, which helps us to understand why the shadow that is thrown upon one object by another may be passed on and accepted as the real shade of the object thus thrown in the shadow, particularly when the shaded object is convex, as are the teeth—which greatly increases their range of power over the plane surface for accepting and reflecting impressions that occur at right angles to the perpendicular, as are the approximal surfaces of teeth, where shade is most apt to occur, and usually does, particularly if that surface be discolored, decayed, or filled. In any event, whatever shade exists in a given approximal space is reflected back and forth from one surface to the other until it reaches a point on the convexity of the tooth that will reflect it to the eye, which establishes the limits of the shade at that point.

For example, a gold and a porcelain filling in contact between the central incisors: The porcelain filling, even though an exact match in color, will appear darkened as soon as placed in a cavity fronting a gold filling, because instead of returning the reflected shade to the gold again, its convexity sends the shadow of the gold to the eye, which gives it a saddened appearance. But if the filling be not scientifically constructed it will absorb a portion of the shadow and return it to the eye by internal reflection, which will make it appear still more darkened. To offset the discrepancy between artificial and natural enamel in transmitting impressions, it becomes necessary, in protecting approximal porcelain fillings against side

shadows to cover the approximal exterior of the filling fronting the shade with a thin layer of opaque white, which practically prevents shadows from entering the filling, thus allowing it to appear as intended, because it cannot reflect a shade that it does not receive.

Reflection always accompanies refraction, which phenomenon causes much of the uncertainty of results in laying on colors, because the enamel being translucent, light passes through it to the pigments, where color is established, and being returned to the eye by internal reflection, in emerging through the enamel it is refracted and reflected at both surfaces of the enamel, and scattered by its convexity. This, in a meager way, in connection with the fact that we cannot see our colors until after the filling is fused and finished, is the reason why the color problem is so mystifying.

A solid body immersed in a liquid having the same reflective index as the solid, vanishes, and light in passing through media of different refractive indices is always reflected, and this reflection may be so often repeated as to render two transparent substances practically impervious to light. An opaque white is produced in this way. The blackest clouds owe their gloom to this repeated reflection, which diminishes the transmitted light when seen from beneath; hence, also, their whiteness by reflected light. Common salt is white from the same cause, and transparent bodies generally, when crushed to a powder—because, though the particles transmit light freely, the reflections at their surface are so numerous that the light is scattered as is sound in echoes. A piece of glass is nearly transparent; crush it, and it becomes an opaque white; wet it, and it becomes semi-translucent. If it and the water were of the same reflective indices, the glass would disappear and the water would appear clear again. This partly explains why a filling of porcelain becomes a trifle more translucent, though a trifle darker after it is set, and becomes filled with moisture from the saliva; it also reveals one phase of the shadow that falls from the cement, in that the dark-

ness of the cement is emphasized by the gloom produced by its repeated reflections in the body of the filling which retains it. It also suggests that the nearer a porcelain enamel can be based upon this plan—that is, two crushed crystalline substances of unequal refractive indices and of unequal fusing-points, the one to be suspended as it were, in the other, as is the crushed glass in water—the closer we will be to the production of an enamel that will come as close to nature as we could ever get, because while it would appear quite translucent, yet it would not transmit light as freely as some of our present enamels, and therefore would be more natural.

INTERNAL SHADOWS.

The only rational plan for controlling internal shadows, which in the main are caused by cement, is to have the latter covered by the natural tooth, so outlining the cavity if possible that the eye will find tooth-substance interposed between it and the submerged cement—between the tooth and filling. Strictly labial cavities are of course not included in this statement, yet they are partially protected in another way, for most labial cavities occur upon the gingival third of the tooth-crown, and the enamel necessary to reproduce nature is very thin at that point. This permits a correspondingly greater amount of foundation body, that if properly made will not transmit much reflection from the cement below it, and the amount that it does show will depend upon how thick the enamel is, for it will transmit such reflection readily, allowing the cement to show through at the margins. Fillings made in this way are affected less by lip shadows than if the enamel be thick or the filling semi-translucent.

In approximal cavities it is usually possible to cut beneath the labial plate, at least slightly, so that the submerged cement is hidden, as it were, below it, to the extent that light, in order to reach it through the filling, must strike the surface of the filling at such an angle that it would be reflected away, so that the tooth

would be lighted by direct rays and appear as intended.

Definite shadows from cement imply that light, after being permitted to pass through the porcelain, must fall upon it, some of the light being absorbed, the diluted remainder being reflected back into the filling and returned to the eye direct, producing a saddening effect. Besides, reflection from the cement is increasingly darkened in proportion to the amount of porcelain the white light traverses in getting to it, and this applies likewise to the shadow.

When a filling is correct before cementation, and looks dead or leaden afterward, it is probable that its changed appearance is the result of light passing through several layers of semi-translucent color-pigment, each one selecting its portion of the white light, thus filling the light that reaches the cement with gloom, which when reflected back through the filling, throws the whole into discord, producing a drab or gray—a color obtained by mixing the primary pigment colors. Such results are possible only when the filling transmits light too freely; because had the light been reflected back by the foundation body after penetrating the colors, as it should if correctly made, there would have been no light to reach the cement, consequently none to be reflected. Therefore the only detrimental effect that could be produced by the cement would be in rendering the filling more opaque and a trifle darker.

Fillings that appear correct from one direction and not from another are not sufficiently protected. This difference in appearance is due to reflected shade, which the faulty construction of the filling permits.

There is probably no way to entirely prevent shadows from being reflected into porcelain fillings, yet it is possible to confine both their extent and intensity to narrow limits, as follows:

First: By cavity formation, in order to conceal the submerged cement.

Second: By using a thin layer of opaque white on the approximal exterior of the filling that will prevent the entrance of reflected side shade.

Third: By making use of a foundation body of the same color and opacity as dentin, having an exterior surface which, being scintillant or faceted like the diamond, will act as a barrier to the

passage of the light in the same way as does salt or crushed glass, which seems the only way of reproducing natural conditions as regards the phenomena of light.

RISE AND DEVELOPMENT OF INTERMAXILLARY FORCE.

By CALVIN S. CASE, D.D.S., M.D., Chicago, Ill.

IN the last May number of the *Dental Review*, under the title "The Intermaxillary Anchorage in Orthodontia," by Dr. Martin Dewey, may be seen one of the many conspicuous attempts to establish the belief that the origin of the disto-mesial intermaxillary force and its modern employment arose with the "new school" of orthodontia.

These frantic efforts, which do not hesitate to deliberately ignore and falsify published data, appear to be due to the childish fear that the new school will lose prestige and strength if any of its members acknowledge, even in the slightest degree, that it is indebted to the so-called "old school" of orthodontia for this foundation principle of its teaching.

Whereas it happens to be a fact—as will be proved in this article—that about ten years before the organization of the "new school" the disto-mesial principle of elastic intermaxillary force arose from a legitimate birth and attended by presentation of the principle at many of the most prominent dental societies of the world, from which it was widely published in proceedings and in the leading dental journals. Moreover, at about this time it had begun to be employed by prominent orthodontists, in exactly the same manner and for the same disto-mesial shifting of occlusal relations of the buccal teeth that has been recently unfurled as the banner discovery of a "new school."

It is with considerable reluctance that I take up my pen for the second time to tell, at this time, all the truth about the origin and development of the intermaxillary force. For I fully realize that the question as to who was the first man to employ this or that method or principle of practice is of very little interest to the profession in general. Nor would I say more than I have said upon this subject, were it not that in addition to the continued reiteration of the most foolish and absurd claims, which were sufficiently disproved in my article published in the May 1904 issue of this journal, it has come to a point where my honesty is impugned and I am practically accused of attempting to steal an honor which belongs to others.

A FANTASTIC "NEW SCHOOL" CLAIM.

Dr. Dewey, it seems, has been chosen to spring the final coup, with the surprisingly fantastic claim the implied gist of which is that Dr. Angle, after all, is the real inventor of the principle of the so-called "Baker anchorage," having published it in 1891, and which, he says, "has been used more or less by Dr. Angle from that time to the present." That some time after the publication of this principle by Dr. Angle, Dr. Baker employed a "modification of it." It is also magnanimously admitted that Dr. Case also employed "this principle as first given us by Dr. Angle"—"probably at

about the same time as Dr. Baker"—but, as he used it only "as an *auxiliary* to an occipital anchorage," and thus "did not grasp the full possibilities of the *principle*," it is implied that he should receive little or no credit, compared with Dr. Baker, who "used the intermaxillary anchorage alone and independent of other anchorage."

The following is a verbatim block taken from Dr. Dewey's article, which will serve as a fair sample of his claims. The italics are my own:

The origin and principle of intermaxillary anchorage was given to us in 1891 and has been used more or less by Dr. Angle from that time to the present.

In 1893 Dr. C. S. Case of Chicago used the intermaxillary anchorage as an *auxiliary* to the occipital anchorage in treating a case of Class III. This case was reported at the Columbian Dental Congress. Dr. Case operated more or less on all the teeth by the use of intermaxillary anchorage, but did not grasp the full possibilities of the principle because he used it as an auxiliary to the occipital anchorage. The principle was the same as advocated by Dr. Angle in 1901.

The first record I can find of the more extensive use of the principle as first given us by Dr. Angle, independent of any other anchorage, was as used by Dr. H. A. Baker of Boston. Dr. Baker accomplished something which had never been done before by the use of intermaxillary anchorage wholly independent of any other form of anchorage. He moved the entire number of lower teeth forward. Heretofore such movement was only accomplished by the method of Dr. Kingsley known as "jumping the bite." When the case was shown to Dr. Angle he became so impressed with the possibilities of the extended use of his principle that he named this form of intermaxillary anchorage the "Baker anchorage" in remembrance of Dr. Baker.

The use to which Dr. Case put intermaxillary anchorage in 1893 was similar to the use by Dr. Baker, except that Dr. Baker used it in Class II, while Dr. Case used it in a Class III case. We also find that Dr. Case used intermaxillary anchorage as an auxiliary to occipital anchorage, while Dr. Baker used intermaxillary anchorage alone and independent from any other anchorage. The use to which Dr. Baker carried the principle of intermaxillary anchorage was farther than Dr. Case went.

This certainly is amusing, to say the least, in the face of the true history of

the intermaxillary force. Dr. Dewey will not even allow that the case which was fully described in a paper, and illustrated with charts and models and the practical apparatus, at the Chicago Dental Society February 2, 1893, and at the International Dental Congress, August 17, 1893, was principally regulated in 1892; nor does he seem to be conscious that I prominently referred to this principle of applying force in papers read before the Illinois State Dental Society in 1894 and 1895; at the Tri-State dental meeting (Ohio, Indiana, and Michigan) in 1895, etc. (In one of these early papers, among other things, I said: "The extending of rubber bands from the extreme buccal endings of appliances attached to the upper or the lower teeth, to points upon the occluding set opposite the first bicuspid, *has become a common one in my practice* in nearly all cases where there is an abnormal antero-posterior relation of the upper and lower front teeth.") And with it all, to finally belittle my use of this force, which he intimates was *only in one case*, he reiterates Dr. Angle's recent claim* that because this force was employed by me as an "auxiliary" to other forces in that case, it lessened its value as a principle of force, and shifted the honor of its discovery to Dr. Baker, whom they well know employed it for the first time several years later. This is especially nonsensical in view of the fact that there is no force in orthodontia that is not used at one time or another as an *auxiliary* to other forces.

*Angle, "American Text-book of Operative Dentistry," 3d edition, 1905, page 753: "To the best of my knowledge and belief we are indebted to Dr. H. A. Baker of Boston for this idea, he having used it in the retraction of the protruded incisors of his son a number of years ago, and it was from him I received the idea. I have hence called it the "Baker anchorage." Dr. Calvin S. Case of Chicago also employed this form of anchorage, probably at about the same time as Dr. Baker; not, however, as an anchorage complete in itself, as did Dr. Baker, but only as an auxiliary to occipital anchorage in a case belonging to the third class. It is reported in the Transactions of the Columbian Dental Congress."

Moreover, Dr. Baker's object in employing the disto-mesial action of the intermaxillary elastics (as will be shown by his own words) was as an auxiliary to aid in forcing the entire mandible forward for "jumping the bite," and not in an interstitial movement "of the entire number of the lower teeth forward," as Dr. Dewey would have us believe; nor for "the retraction of the protruded incisors," as Dr. Angle now sees fit to characterize it; though both of these movements doubtless occurred to a slight extent during the short time it was employed by him practically in that case, in which he claims to have produced the desired movement "in two months' time."

CLAIM REFUTED BY THE TESTIMONY OF THE BENEFICIARY HIMSELF.

I am pleased to say that there is no direct evidence to show that Dr. Angle had anything to do with this and similar efforts from the pen of his college assistant, Dr. Dewey, especially as he has always disclaimed—even in his last writings—any knowledge of what we understand as "intermaxillary force" or anchorage, *until the idea was given to him by Dr. Baker*. Even if he were inclined, his better judgment would hardly permit him to attempt working off his simple expedient published in 1891 (which was for the liberation of impacted labial teeth with rubber ligatures to the lower teeth, or direct intermaxillary force) as the origin and "principle" of the disto-mesial intermaxillary force; especially as by his own acknowledgment he never attempted to employ it in this way until about ten years afterward—notwithstanding Dr. Dewey's inference to the contrary. And during this time he did not even associate his device with the disto-mesial action of intermaxillary elastics which he must have been aware was being employed by others, and which he afterward published as "a novel method of exerting force," *thus acknowledging it as a distinct principle by naming it the "Baker anchorage."*

One might with equal propriety claim that the operations of extruding

the teeth—or any of the lengthwise movements—are of the "same principle" as retruding the teeth—or any of the lateral movements—on the basis that both movements may be accomplished with similar devices from anchorages upon the same denture. Or one could claim that all of the intermaxillary forces—some of which have been employed for many years—such as wire and other ligatures for holding fractured jaws closed; intermaxillary springs for supporting artificial dentures; Wilder's intermaxillary socket-and-ball device for correcting irregularities, etc., are all of the "same principle" because they are dependent upon the opposing jaw for a sustaining anchorage.

Some time in the latter part of the '60's, Dr. Jerry A. Robinson of Jackson, Mich., with whom I was studying dentistry, tied a silk ligature from a partially erupted central incisor to a narrow strip of plate swaged to fit the labial surfaces of the lower front teeth, to which it was tied, for the purpose of bringing the tooth down to the occlusal plane. The patient was a boy about fifteen years of age who was living in his family. The ligature was cut at meal-times and replaced immediately afterward. It required only a few days, as the desired movement was not great; after which the tooth was tied to the adjoining teeth for retention. He did not claim that it was anything new or original, and I was led to believe that this was the ordinary way of correcting this malposition. But was it not the "same principle" that Dr. Angle employed in 1891, except that the latter used the excellent and important modification of *elastic* ligatures, which could be more conveniently adjusted and worn?

So one could keep on with this sort of reasoning to the profound and truthful conclusion that *all* movements of teeth, and devices for that purpose, are but *modifications* of some similar action or principle, as are all mechanical devices for the application of force everywhere but modifications of principles outlined in Newton's laws, and originally employed by nature and God, to whom consequently all the honor belongs. For that matter,

throughout all the ages since the advent of man, the elastic intermaxillary force has been constantly and successfully employed in the correction of malocclusion of the teeth through the action of the muscles; and moreover, by forcing the teeth into normal and interdigitating occlusion by a *reciprocal disto-mesial movement* of buccal cusps. I suppose there are in the world men so blinded with a little knowledge, with a tendency to rush in where angels are scarce, as to attempt to prove that this was but a modification of a principle originally employed by some man, if they could manage to antedate it by a string of half-told and adroitly juggled events.

From which may be gleaned the fact that *direct* intermaxillary force for the pulling downward of upper labial teeth is no more like the *disto-mesial* intermaxillary force for the shifting of occlusal relations of all the teeth, than are other forces whose actions differ both in principle, action, and direction.

SOME PROFESSIONAL COURTESIES AND OTHERWISE.

There was one very unusual coincidence in connection with this article by Dr. Dewey, which I shall leave my readers to elucidate: A few weeks after the receipt of the manuscript by the editor of the *Dental Review*, he also received the MS. of another article in attack upon me and my claims. Both of these were received during one month; both were along similar lines; and both were signed by Dr. Martin Dewey. The last one was so offensively personal in character that it was refused by the *Review* and afterward by the *Items of Interest* and by the *DENTAL COSMOS*, although (after being permitted to read the MS.) I urged these journals to publish it verbatim, and I also mailed similar requests to other journals should they receive it. My delay in answering the first of these efforts has been due to the feeling that I might be able to kill two birds with one stone, and thus save a lot of valuable time. The last one was in the form of an open letter "To Dr. Case." In one place it ac-

cused me of not remembering, "because you wanted to forget," that Dr. Angle was the originator of the intermaxillary force!

To show whether or not I have earnestly desired to give credit wherever it is due, one has but to read the published correspondence in the May 1904 *Cosmos*, in which I tried by every means in the power of a gentleman to obtain some authentic data for the origin of this principle other than that which I had so widely published years before; promising to "apologize publicly if I find that an apology is due."

The following circumstance will further show my intended fairness—which should put some of the published and unpublished accusations of Dr. Dewey and others to shame:

Soon after mailing the MS. of the article entitled "Origin, Use, and Misuse of the Intermaxillary Force"—which was published in the *Cosmos* for May 1904—in looking over some old journals I chanced upon Dr. Angle's article of September 1891, published in the *Cosmos*, entitled "Forcible Protrusion of Non- or Partially Erupted Teeth." I then remembered to have seen it in some of his later publications, but, like Dr. Angle, I had never associated it with that which we understand as "intermaxillary force." Thinking, however, that others might see a relation, I immediately wrote the following request to the editor of the *Cosmos*:

April 18, 1904.

Will you please insert the following paragraph at the *very head of my article*—or in a footnote at the bottom of *that page*, viz:

"In the September 1891 *Cosmos* Dr. Edward H. Angle published the unique method of bringing down impacted upper cusps with rubber ligatures attached directly to the lower teeth, and consequently he was probably the first to publish the application of the elastic intermaxillary force used in this way."

Dr. Kirk replied (April 22, 1904): "It comes too late for me to make the change you desire. I shall, however, write a brief editorial calling attention to the matter."

To this I wrote the following reply:

CHICAGO, ILL., April 25, 1904.

Dear Dr. Kirk,—Yours of the 22d inst. received. I am awfully sorry you could not make the change I suggested, especially that in reference to Dr. Angle.

I had known for some time that Dr. Angle published the use of rubber ligatures from impacted cuspids to the teeth of the opposing jaw, but had never associated it in the slightest degree with the principles of the "intermaxillary force" which I had been publishing. But just before writing you, in looking over some old *Cosmos*, I found much to my surprise that he had published it in 1891, and wishing to give him every credit that is his due, I immediately wrote you to fix my article as it would have been had I seen this before. Therefore, doctor, will you please be sure to quote me exactly in your editorial where I ask you, in a letter of April 18th, "to insert the following paragraph at the very head of my article," etc., followed with the paragraph; and greatly oblige.

The said paragraph duly appeared in the editorial columns of the *Cosmos*, and so far as I am able to learn it was the first time that Dr. Angle's device had been named an "intermaxillary force." Up to this time all of the members of the "new school," including Dr. Angle himself, had spoken of the disto-mesial action of this force, as the "Baker anchorage." And though Dr. Angle in one place claims it as a modification of his device, if he had really believed it to be the same "principle" when he published his book, would he have given the credit of its discovery to Dr. Baker in the manner that he did?

It should be remembered that at the time this was published (October 22, 1900) in the first edition of a text-book entitled "Malocclusion of the Teeth and Fractures of the Maxillæ" (which for some reason is called the "sixth edition") the "new school of orthodontia" was not born, and its prospective members, who may have been more or less acquainted with my earlier writings, had not discovered, or at least did not believe in the main uses of the intermaxillary force, which was pointed out to them later by Dr. Angle, and on this account was naturally regarded by them as a new and "radiant star" discovery.

In an address delivered by Dr. Angle

before the New York Institute of Stomatology on October 2, 1902, and published in the *International Dental Journal* for October 1903, in speaking of the possibilities of this force and the advantages of moving teeth to normal occlusion as opposed to extracting, he said: "This form of treatment I have been practicing now *but three years*, and so pleased am I with it in the large number of cases I have so treated that I no longer practice or believe in the plans that I formerly advocated," etc. This establishes the date of his first employment of the disto-mesial action of this force at not earlier than October 1899.

I have been credibly informed that the only practical use which Dr. Angle made of this force up to the latter part of 1900 was the same as that for which Dr. Baker had been using it, i.e. "jumping the bite;" and that it was Dr. L. S. Lowrie of Chicago, who was then a teacher in the Angle School, who first called his attention to the distal movement of molars, which led him to finally try the interstitial disto-mesial action of the intermaxillary elastics, and to the proclamation two years afterward of "the large number of cases I have so treated."

To prove that Dr. Angle did not recognize or appreciate the full possibilities of this force much before 1901 one may read his book ("sixth edition") from cover to cover, and he will find nothing in regard to this force except that in connection with Dr. Baker's "novel" employment of it. And though he here mentions its disto-mesial possibilities, he must have had little or no experience of its value in this regard, else he would not have advocated, as he does in the *paragraph immediately following* this description, *the extraction of the first bicuspid in a simple case of mal-eruption of an upper canine*, which he illustrates in his "Fig. 262" (see next page).

Of this sort of treatment I cannot help but somewhat irrelevantly remark that, years before this publication, many members of the so-called "old school" who had learned by much experience the powers of the intermaxillary force, would have considered this treatment the rank-

est kind of malpractice—as the illustration shows. Why? Because if the teeth are in normal occlusion upon one side and the facial outlines are not protruded,

—Angle. (Fig. 262.)

it is *prima facie* evidence that the mal-eruption of the canine upon the other side is due to a *local* cause, and probably to the premature loss of deciduous teeth, thus permitting the canine space to be closed, principally by a drifting forward of the buccal teeth to a malocclusion, and partially by a lateral shifting of the incisors toward that side, commonly followed with a contraction and consequent mal-alignment of the lower arch. Therefore all cases of this character *demand* that they be corrected without extraction by forcing the teeth back to normal relative positions and occlusion, thus opening the space for the eruption and normal alignment of the canine, else the adult facial outlines will be invariably marred. Let us hope that Dr. Angle will expunge this method of malpractice from his "seventh" edition.

SOME ACTUAL HISTORY.

Now let us turn back a few years and examine the earlier history, from authentic standpoints, of this much exploited and abused intermaxillary force. During the summer of 1891 I was consulted in reference to a case of regulating by Dr. Geo. W. Haskins, a prominent Chicago dentist and skilful orthodontist, who has filled a number of honorable positions as teacher and professor in the

dental schools of Chicago. The case was that of a lady about twenty-five years of age. The lower left buccal teeth had drifted forward, protruding the canine. The lower first molar had been extracted, leaving only one molar, which was too unstable to afford sufficient anchorage strength to force the bicuspid and canine back to a normal occlusion with the uppers, which the case demanded. In addition to a very ingenious appliance which the doctor had constructed I at once suggested the employment of intermaxillary elastics attached to the distal extremity of an upper molar anchorage—a method which (he will remember that I told him) I had employed in a number of cases of my own. Nor would I be surprised to learn that others, even years before this, had employed the same principle of force, because it is so simple, and the opportunity when suggested by the need is so evident that it would seem that any child might think of it.

Soon after the prominent introduction of this force by me, February 2, 1893, and later, I presume there were many others besides myself who began the extensive employment of it for the disto-mesial correction of malocclusion. Dr. A. E. Matteson, a prominent orthodontist of this city, writes me in answer to a letter of inquiry: "It is a fact that I was using the maxillary elastics quite extensively in 1894 for the correction of occlusion." In the same letter he gives the record of a number of cases of which he has the casts. He has since made the following statement:

I was present at the reading of Dr. Case's paper before the Chicago Dental Society February 2, 1893, in which he introduced for the first time two important principles of force for the correction of facial deformities, i.e. the anterior and posterior movement of the roots of the labial teeth, with what he termed the "contouring apparatus;" and the reciprocal anterior and posterior movement of the upper and lower teeth and jaws, with the intermaxillary force. I was exceedingly interested in the practicability of the intermaxillary elastic ligatures. In the discussion, Dr. Black put into my head the idea of employing this force for the disto-mesial movement of the buccal teeth for the correction of occlusion; the outcome of which induced me to at once

commence quite an extensive employment of this principle, both in my private and clinical practice. A record of these cases I am now prepared to show.

I then held the chair of orthodontia in the Northwestern University Dental School. In the fall of 1895, the university having absorbed the American Dental College, I resigned my position, and Dr. E. H. Angle, who was professor of orthodontia in the American Dental College, was continued at the head of this department, with Dr. J. N. MacDowell as his assistant; with the result that my clinical patients who were wearing the intermaxillary elastics were obliged to pass into the hands of the new *régime* for the continuation of their uncompleted work.

Dr. J. N. MacDowell, author of a textbook entitled "Orthodontia," and now professor of orthodontia in the Illinois University Dental School, has informed me that he remembers very well Dr. Matteson's clinical patients who came to the infirmary of the N. W. U. D. S. in the winter of 1895-96, and that some of these patients were wearing the intermaxillary elastics for the correction of malocclusion. When Dr. Angle's attention was called to these cases he ordered the appliances removed and replaced with his own, with the remark that that was some of Case's and Matteson's ineffective methods (which is to tell only a small part of this story).

From the above episode it is reasonable to infer that Dr. Angle *did* know of the disto-mesial employment of the intermaxillary elastics long before Dr. Baker told him of its effective action in "jumping the bite," notwithstanding his repeated publications to the contrary. If he disliked to admit that the honor of its invention belonged to the writer—in accord with his own statement in the preface of his book ("sixth edition"), "To fair minds recorded dates are usually sufficient evidence of priority"—why should he not have given it to Dr. Matteson, whose appliances utilizing this force he so peremptorily ordered removed, and which were placed there, as Dr. MacDowell has said, evidently for the purpose of a disto-mesial interstitial shifting of the buccal teeth to a normal occlusion? Or why should he not now give it to Dr. Haskins, who employed this principle in

1891? Or to Dr. Black, who suggested its wide possibilities in 1893?

I now wish to call attention to some of the evasions of truth which were employed for the sole purpose of establishing a false belief in regard to the origin of an important principle in orthodontia, leaving my readers to judge of the honesty and manliness of these methods. Space will not permit me, at this time, to detail the many examples of these efforts which apparently have arisen through the encouragement or instigation of the principals, and I will speak of but few of the many shameful attempts to suppress the truth by those who were in full possession of published data which established its validity.

SOME STATEMENTS BY DR. ANGLE EXAMINED.

The long correspondence that ensued between Drs. Angle, Baker, and myself, a part of which was published in the May 1904 DENTAL COSMOS, and which arose from an earnest endeavor on my part to find legitimate data—if it existed—for the term "Baker anchorage," speaks for itself as a striking example of evasion. Among the early replies to my many letters of inquiry is the following from Dr. Angle (November 17, 1903):

I am sure he (Dr. Baker) has been using his method of anchorage for fifteen years, as I saw patients in his office now grown up, on whom he used it in their childhood.

How long does it take for a patient of twelve or fifteen years of age, upon whom he would naturally apply this force, to "grow up"? The only case of Dr. Baker's which could possibly answer to the "patients" whom he said he saw was Dr. Baker's youngest son, Warren, who was "grown up," or eighteen years of age on August 21, 1899 (the year that Dr. Angle first commenced to use the so-called Baker anchorage for jumping the bite, as will be shown). But Dr. Baker does not say that Dr. Angle *saw* any of his patients at this interview. In his letter to me of November 24, 1902, he says:

When he (Dr. Angle) first came to see me about my system of orthodontia, I gave this

method to him, among others, as my invention. I informed him that I had used it with the very best results. He was a little skeptical as to its efficacy, but said he would try it, which he did in eight or ten cases before publishing it.

If Dr. Angle saw even the one case of Dr. Baker's son in 1899—after it was "grown up"—with its results as he published it in his book the next year, why should he be "skeptical as to its efficacy"? Moreover, Dr. Baker has said (as will be shown) that he corrected this case *in a few months' time*, and therefore it may have been corrected only a very few years before this event. *I am credibly informed that Dr. Baker did not practically employ the intermaxillary force in this or any other case until some time after November 1, 1895.*

Then why should Dr. Angle, with no real evidence whatever, say, "I am sure he has been using his method of anchorage for fifteen years." Would any man whom we would delight to honor make a broad statement of that kind with no evidence in his mind to prove it, and without some deep intent to deceive and silence me? Would such a man, in writing a text-book, give the whole credit of the origination of an important principle of force in orthodontia to one man, who had happened to tell him about it the year before, and not even mention the name of another who had widely published it eight years before, and in one instance at an International Dental Congress which he attended? He certainly must have known of it in the winter of 1895-96 when he ordered Dr. Matteson's appliances removed. Moreover, would such a man, in 1905, with every data of the truth before him, and fully conscious of his own words—"To fair minds recorded dates are sufficient evidence of priority"—publish in his chapter in the "American Text-book of Operative Dentistry," third edition, the foot-note on page 753?

SOME REMARKS ON DR. H. A. BAKER.

Now let us turn to a few of the acts of Dr. H. A. Baker of Boston. In one of his replies to my request to—"Kindly di-

rect me to the periodical or text-book" where he "first published the idea" of the intermaxillary force, he gave as one reason for his refusal that it "*would be considerable trouble in looking up the records of the different societies throughout New England.*" Yet he KNEW there was only one time and one place that he had publicly mentioned this method of force, and then in a very incidental and problematical manner, with no appliances or even drawings of the device, but merely as *something he was going to try* (as will be shown); and in no wise was it in the sense of bringing before a society an original idea of value, for the purpose of having it recorded as a new device as he has claimed. In fact, as he made no claim at this time to the originality of this principle of force, it is natural to presume that he obtained the idea from the two prominently presented papers in which it was described months before. His mention of it occurred at one of the regular monthly meetings of a Boston local society—"The American Academy of Dental Science"—on Wednesday evening, December 6, 1893.

The subject of the evening was "Orthodontia," and consisted mainly in a discussion of Dr. Geo. C. Ainsworth's methods of regulating teeth (which Dr. Baker had adopted) and Dr. Baker's methods of retention. Dr. Baker opened the subject as follows: "Mr. President and gentlemen,—Dr. Ainsworth and I *do not claim to bring anything new before this meeting.*" Here followed quite a lengthy discourse upon a system of regulating proposed by Dr. Ainsworth, which had nothing to do with intermaxillary force; and a spur method of retention by Dr. Baker.

The only reference which could be construed as relating to the intermaxillary force during the entire evening occurred while Dr. Baker was exhibiting the models of cases. And as this incident is absolutely the only evidence upon which can be made to hinge the right to apply the term "Baker anchorage" to the intermaxillary force, I will quote the whole of this record exactly as it appeared under "Reports of Society Meetings" in the

International Dental Journal for April 1894, that the reader may see how very unimportant he considered the intermaxillary feature of this exhibit:

Nearly all these cases have been regulated by means of Dr. Ainsworth's band. This case has a right central turned a quarter way around, and a right cuspid placed outside of the arch. The irregular teeth are now in good line, and held in position by spurs. Here is another case which is very much out of line, both as regards the upper and under teeth; the upper ones only have been regulated, and are now held in place by retaining spurs. Here is another case, in which the right cuspid is very much out of line, and the arch contracted. In this case I used the band in connection with the spur as a retainer. This case shows a separation of the front teeth. The under teeth seemed to throw the upper ones out, making a space of about one-sixteenth of an inch between the incisors. This condition was corrected by the use of the band, which threw back the front teeth, both upper and lower. These teeth were retained in position by a wire hook passing around the upper centrals. I do not claim that they will remain in place. There is a cause for the separation of these teeth, and I do not know whether or not there is any remedy for it. I have here a bad case of protruding upper jaw, or a much receding lower one. This case is in my own family, and no one wishes it corrected more than I do. My plan of treatment is to put in place bands on both upper and lower teeth, and spread the arches by tying to the bands all the teeth in front of the molars. Then to take four square nuts and solder a hook to each, and screw them on to the bands. Elastics are to be slipped over these hooks. The child is to wear the appliance constantly. You will see that the tendency of this arrangement will be to draw the upper jaw back and the lower one out, and so jump the bite. I don't know whether this apparatus will interfere with eating or not. I will try to explain on this model how teeth are retained by spurs. The right central and right lateral are both twisted. The right central was turned to place, and a spur put in the mesial surface of the right lateral, the spur holding the central in place. After twisting the right lateral to place, it was retained by drilling into the distal side of the right lateral and putting in a spur which rested on the cuspid. Another spur in the mesial surface of the right central rested on the palatal surface of the left central.

The few indefinite and doubtful remarks in the above quotation in regard to

the intermaxillary force are the only ones I have been able to find which Dr. Baker made before any dental society, up to his paper of nearly ten years afterward, to which I shall refer later.

At the time of the said meeting in Boston, Dr. Baker was practicing dentistry in the office of Dr. Ainsworth. I am credibly informed that the models of his son's teeth to which he referred were at some time after the meeting set up on an articulator with the intermaxillary elastics tied to appliances constructed by the elder Dr. Moffit, in which state they remained on Dr. Baker's desk, and were *not put into practical operation during the time he remained in that office*—which he left November 1, 1895.

At the meeting of the Stomatological Society of New York City, January 6, 1903, Dr. Baker presented the first and only paper that he has ever written relative to the intermaxillary force. This was published in the *International Dental Journal* for May 1904.

In speaking of the origin of the method he says:

My youngest son was afflicted with a very pronounced case of protrusion and recession of the jaws, for which I studied out a course of treatment which I thought would be effective. I brought my study model before the American Academy of Dental Science, and explained my method; *after which* I proceeded as I explained, and carried the case through.

Farther along in his paper he says:

While studying these models, by sliding the lower jaw forward so that the sixth-year molars would be in a normal occlusion, I found that with a very little spreading of the arches and slightly retracting the upper incisors I would get proper occlusion. By close observation we noticed the deformity is confined to more of a recession of the lower jaw than protrusion of the upper. As the correction requires very little tooth-movement and considerable forward bodily motion of the lower jaw, it was a great problem to me what force to apply to produce this result. . . . I took my models before the American Academy of Dental Science and explained my method of procedure, requesting it to be put on record as a new device for correcting protruding and receding jaws. I commenced the case in the spring of 1893. I was astonished with the result. In two months' time the

teeth were occluding in a normal position; but for fear that they might return to their former position, I reduced the size and strength of the elastics and kept them in that way several months longer, and by so doing they settled into perfect occlusion. The next step was to retain them.

Though he twice refers to the event of his bringing the idea before the American Academy of Dental Science for the purpose of recording the origin of this method, yet he studiously avoids stating the *date* of that meeting, thus with the apparent intention of leading one to infer that the meeting must have occurred some time before 1893, as he claims to have "commenced the case in the spring of 1893"—but *after* the said meeting, at which time he said, "I don't know whether it will interfere with eating or not." As this meeting did not take place until December 6, 1893, according to his own acknowledgment he could not have commenced the case before the spring of 1894. And as it took him only a few months to complete the operation, he may not have commenced the case until the spring of 1896, and still have had plenty of time to show it to Dr. Angle in 1899, when the patient was "grown up" (which is somewhat less than "fifteen years").

I do not say that Dr. Baker's idea of the use of the intermaxillary elastics did not originate in his own mind. That would not be so very strange. But it nevertheless is not a far cry to say that on December 6, 1893, when he told how he intended to try the method as an auxiliary to other forces in the regulation of his son's teeth, it was not impossible, or even unnatural, that he should have already heard of it from the two papers read at prominent dental societies during the earlier part of that year, in which this principle was fully described and illustrated, and which he may have had in mind when he said, "I do not claim to bring *anything new* before this meeting."

REDUCTIO AD ABSURDUM.

Now, note—First: The difference in the time and character of the two pre-

sentments of this principle by Dr. Baker and myself.

Second: The fact that the principle was repeatedly referred to by me during the two subsequent years, in papers read before the most prominent dental societies of America, whereas with the exception of the event December 6, 1893, and the fact that he "told" Dr. Angle about it in the latter part of the '90's, there is no record of any attempt on Dr. Baker's part to publish the method until after January 6, 1903.

Third: At the time and before Dr. Baker practically applied this principle for jumping the bite in the regulation of his son's teeth, a number of prominent orthodontists were extensively employing it in their practice for the disto-mesial interstitial shifting of occlusal relations of the buccal teeth, in exactly the manner and for the same objects which many have been led to imagine originated very much later with the "new school"—in which it forms the foundation of all that can be claimed as new.

Fourth: The first employment of this principle of force by Dr. Angle, according to his own words, was not earlier than October 2, 1899, and then for a year or more he used it principally, if not solely, in operations of jumping the bite.

When all of these truths are calmly considered, do they not make Dr. Dewey's statements sound silly? And yet I am informed that he is a man of considerable intelligence and a pretty good all-round fellow, when allowed to think and speak for himself.

I had hoped that my first defense—the truths of which have now stood for three years unchallenged—would be considered sufficient to stop these ridiculous vauntings, but as that evidence has been completely ignored in certain quarters, with a constantly increasing tendency to suppress and pervert the truth, it is with the deepest regret that I am now forced to publish such a shameful commentary on professional honor and ethics.

SETTING CROWNS AND BRIDGES WITH GUTTA-PERCHA.

By L. G. NOEL, D.D.S., Nashville, Tenn.

(Read before Section I of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

IN crowning teeth whose roots have been in a condition of septic inflammation, a method of setting crowns that will admit of easy removal for further treatment has been earnestly desired, but not yet fully realized.

Other conditions may arise aside from dento-alveolar abscess or pericemental inflammation rendering it desirable to remove the work, such as a fractured facing or a desire to make changes in occlusion. Removal is well-nigh impossible when the work has been attached with zinc oxyphosphate cement.

Gutta-percha possesses qualities that recommend it especially for either permanent or temporary settings, being readily softened by the application of heat; but the obstacle in the way of its general adoption has been the difficulty of dissolving it so as to obtain it in a cement-like consistence.

Nothing can be more disappointing than a failure to carry to place a crown or bridge which has been carefully adjusted, for this will certainly derange the occlusion. The difficulty has been stated with almost all the preparations of gutta-percha with which your essayist has experimented, except the old solution in chloroform, which is too unsatisfactory to merit a second trial. It shrinks notably when the solvent evaporates, leaving a mere string in the canal, which furnishes no support to the work.

Encountering these difficulties, I set to work, hoping to obtain a solution that would have sufficient body to control the shrinkage and at the same time possess an easy flow under pressure, like that of soft cement. I think I have succeeded in obtaining a fairly good solution, and

with it have had results that have been highly gratifying to me. I offer it to you for what it is worth, fully realizing that is by no means perfect, and that my own experiments are too recent to go on record as final. I hope you will take it up and give it a trial. Perhaps some of you will improve upon my ideas, in order that we may thus arrive at something truly good.

At present, I am proceeding as follows. Make the following solution of gutta-percha:

Chloroform,		
Oil of eucalyptus,	āā f3j;	
Aristol,	gr. xx;	
Gutta-percha, q. s.		M.

This solution should be made in a wide-mouthed bottle and the stopper smeared with a little vaselin to prevent the evaporation of the menstruum, and also to make it easy of removal. It will take about a week to obtain a satisfactory solution of the gutta-percha, and it should be stirred from time to time until all lumps have disappeared, adding more gutta-percha, if necessary, until a creamy consistence is obtained. I prefer the red base-plate gutta-percha cut in small pieces.

As the mercury sulfid which this variety of gutta-percha contains renders this preparation to a certain extent antiseptic, apart from the aristol, which is markedly antiseptic, no trouble will arise if a little should be forced through the apical foramen.

Now, when ready to set a crown or bridge, pour a sufficient quantity of this solution upon a slab, and with a strong spatula work into it a quantity of white zinc oxid, spatulating it thoroughly, and

adding a little of the powder at a time, until the consistence of cold butter is obtained. The root-canals may now be filled by carrying in small quantities of it at a time with smooth broaches; the caps and crowns should also be filled, and the work carried to place.

This preparation has a smooth, oily, butter-like flow, and the excess will escape easily from the caps and crowns. The powder accompanying the zinc oxy-phosphate cement will do as well as the

pure zinc oxid. The gutta-percha undergoes a hardening process as time passes. This has been said to be a process of vulcanization, as it seems to be something more than a mere evaporation of its solvent. If it become desirable to remove the work, a little heating of the gold by applying the bulb of an Evans' root-canal dryer, which has been previously heated in a Bunsen flame, will soften the gutta-percha, and the work can be readily pulled off.

METHOD OF TAKING IMPRESSIONS FOR PORCELAIN AND GOLD INLAYS BY MEANS OF STRIPS OF ALUMINUM IN COMBINATION WITH DENTAL LAC.

By IRA G. BAUMGARDNER, D.D.S., São Paulo, Brasil.

THE unsatisfactory results often obtained by the burnishing of platinum into cavities for forming matrices led the writer to experiment in taking impressions by means of dental lac. The idea was not a new one when applied to buccal restorations or cavities of direct approach, and for these the manufacturers supply cups or forms nicely adapted to the purpose; but for approximal or compound cavities, no adequate solution has been offered to meet these requirements.

Dental lac is a most excellent material for impression work, giving a faithful image of cavity and margins, and reproducing in the die of inlay metal a perfect counterpart of the cavity; but the question was how to use it in approximal cavities in the absence of a proper vehicle to confine it. Cloth polishing tapes were tried, a small button of lac being warmed and attached; the strip was then drawn between the teeth and pressed to place; but this, however, did not afford the necessary rigidity. Strips of German sil-

ver and brass, very thin and well annealed, were likewise tried, but their springiness would not allow the lac to set in place and stay set. Finally, aluminum was tried, and unfailing success with it during the past two years has encouraged the writer to recommend its use in taking impressions for stamping the matrix, and as being applicable to all cavities in the interproximal space, of whatever shape or position.

Aluminum when well annealed is softer than lead, can be rolled to the thickness of paper, and when bent remains in the position to which it has been adapted, and by its use, in combination with dental lac, an inlay of gold or porcelain can be placed with comparative ease (having the necessary separation) in approximal cavities in the molars, if so desired.

Strips of aluminum plate are rolled out to No. 34 gage—and thinner if desired—cut in lengths of about $1\frac{1}{2}$ inches, and in width slightly larger than the cavity measured from the gingival to the

occlusal wall. (Fig. 1.) When the cavity extends to or under the gum, the strips are cut with an extension (Fig. 2), to insure the lac reaching and recording

cessity to press away the gum with cotton or gutta-percha beforehand, as the gum extension on the strip, passing beyond the limits of the cavity, will give in the

FIG. 1.

Plain aluminum strip.

FIG. 2.

Aluminum strip with gum extension.

FIG. 3.

Aluminum strip with occlusal extension.

FIG. 4.

Aluminum strip with gum and occlusal extensions.

this margin. In all cavities involving the biting edge, whether in the anterior teeth, the bicuspid, or the molars, or where corners are to be restored, an occlusal extension is cut and bent over at a right angle (Fig. 3), in order to include the occlusal surface.

lac a perfect impression of this margin, so difficult of attainment by burnishing the matrix.

In taking the impression the cavity is first moistened with cold water. Then to the center of an aluminum strip—cut to requirements—is attached, by gentle

FIG. 5.

Strip and impression of cavity.

FIG. 6.

Inlay on die of inlay metal ready for undercutting or etching.

Good separation is, of course, always desirable for porcelain work, but for this method very little, if any, additional separation is needed beyond that required for the burnishing process. One great advantage in the use of these aluminum strips will be found in cavities extending to or under the gum, for unless the gingival wall is seriously lost, there is no ne-

heat, a button of dental lac—a quantity just sufficient to fill the cavity and give a slight marginal excess, and covering well any gum or occlusal extension—and after heating in a spirit lamp to the desired plasticity, the strip is drawn between the teeth, and the lac firmly pressed to place, the ends of the strips being drawn round palatally or buccally,

if these walls are involved. When an occlusal extension is used, an assistant is necessary to press this down with a blunt instrument, in order that the underlying lac may be well adapted. After a half-minute for setting, cold water is poured from a syringe, the pressure is released, and the impression removed. (Fig. 5.) The ends of the strip are snipped off close to the lac impression, and it is then embedded in moldine and is ready for pouring the die of inlay metal, followed

by the stamping process. If a platinum matrix be stamped from the die, no further trying-in is necessary, unless to verify contour or shade until the porcelain or gold inlay is ready for insertion; for if the procedure of taking the impression has been carefully carried out, the inlay will fit. (Fig. 6.)

The simplicity of the method makes it a time-saver in impression-taking, and with an entire absence of strain on the patient or operator.

PROSTHETIC NOMENCLATURE.

By **GEORGE H. WILSON, D.D.S.,** Cleveland, Ohio.

(Read before Section II of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

ALL agree that dental nomenclature is imperfect; but there is considerable variance of opinion as to how it can best be improved.

As any language consists of the diction of its best authors and teachers, so the phraseology of a profession consists of the diction of its authors and teachers. The permanence of a vocabulary depends upon the accuracy of the formation of words and whether they best express the thought for which they are used. There are words in the dental vocabulary universally used that cannot endure for all time because their literal meaning is entirely foreign to their accepted use. As illustrations "canine" and "arch" are cited. "Canine" is now discarded by a very respectable portion of the profession; later we shall show wherein "arch" is an inappropriate word as now applied.

Modern dentistry is a young profession and still in a formative state, but far enough advanced for much good work to have been done toward perfecting its nomenclature. The work of Dr. Black pre-

sented at the Second International Dental Congress in 1893 and the reports of Dr. Guilford and his committee to the American Dental Association in 1895 and 1896 were an excellent foundation for this department of dental education.

There seems to be a lack of courage with some of our most ardent workers in this department of dental knowledge; so much so that they advocate compromise with error for the sake of harmony. (See report of the Committee on Nomenclature in the Transactions of the Fourth International Dental Congress.) There can be no permanence established upon compromise, only time and labor lost. Therefore any changes advocated to give assurance of endurance must be scientifically considered and must be the very best known to the professional mind. Prejudice, pride, and euphony should all give way to philology; then, and then only, can any permanent work be accomplished.

The argument has been made that we cannot legislate a nomenclature into ex-

istence. This is true, but we can do what will be its equivalent in a few years. The National Dental Association and the National Institute of Dental Pedagogics include in their membership the authors and teachers of the profession, therefore a well-considered vocabulary adopted by them will be adopted by the three avenues of education—the schools, the journals, and the writers. After a few years the old, who cannot learn, will have joined their fathers, and the improved vocabulary only will be in existence. If the dental profession has a vocabulary bearing the official stamp of its two national bodies, it will undoubtedly be adopted whenever there is a revision of our standard literary and medical dictionaries.

Appended to this paper [p. 460] is a list of words especially used in prosthesis. They are arranged alphabetically and are marked to show when approved by the Standard and Gould's dictionaries. The pronunciation is that of the N. D. A. committee of 1895-96, as given in their list. If there is a special dental application of the word, credit is given for the definition to the person responsible for its existence, when known by the writer. Many of the words listed need no comment, while others require discussion. The words for special consideration will not be taken up in alphabetical order but as they seem to the writer to group themselves.

Various names have been applied to this department of the profession: Prosthesis, Prosthetic Dentistry, Prothetic Dentistry, Prosthodontia, and Mechanical Dentistry.

Pros'-thes-is—Standard and Gould; *pros'-the-sis*—committee of 1895. Gk. *pros*, to, *tithemi*, to place. Defined: The making of artificial parts and fitting them to the body, as artificial teeth, cork legs, glass eyes, etc.

What authority the committee of 1895 had for changing the pronunciation from "pros'-thes-is" to "pros'-the-sis" does not appear, but certainly it is much easier to pronounce and should be adopted.

This noun was probably long used by the medical profession before it was taken up by the dental, but its use is

very limited by the mother profession compared with the dental, therefore it seems no presumption for the latter profession to appropriate and give it a special significance. It is comparatively a short word, and is that generally used throughout the profession, especially in its adjective form, to denote making and inserting artificial dentures. It is a general term, therefore is capable of assuming any shade of meaning the age may require; hence it is the best term yet suggested for this branch of the profession.

Definition: Prosthesis is the science, art, and esthetics of restoring a lost dental organ or organs and associate parts with an artificial substitute. Science is the theoretical knowledge of the subject, art is the skilful doing of the work, and esthetics is the idealizing or harmonizing of the restoration.

The term or name accepted should not be confined to the teeth, because to-day they are only a small part of what is covered by this department of dentistry. Appliances for cleft palates, dental splints, and even lips and noses may be required of the dental prosthetist. However, the most important esthetic service the dentist is required to render is to restore the contour and expression of the lower third of the face.

Pros-thet'-ic dentistry. A proper term, but long, and one rarely necessary, especially if the appropriating of "prosthesis" is approved.

Pro-thet'-ic dentistry. "Pro-thet'-ic," adjective form of "proth-es-is," Gk. *pro*, before, *tithemi*, to place. A term rarely used, and it should not be put in the dental vocabulary.

Pros"-tho-don'-tia. From two Greek words, *prosthesis* and *odontia*, meaning "to place" "tooth," but as applied to dentistry the word is made to cover all work done by the prosthetist.

The derivative is good, but literally it calls attention to the smaller part of that to which it is applied; therefore it is misleading and tends to make ignoble this most complicated and difficult part of our profession.

Mechanical dentistry. The first name given to prosthetic dentistry; but it

should now be restricted to the work done in the laboratory, whether for the prosthodontist, orthodontist, or operator. The mechanical dentist works for the dentist, not for the patient.

"Cast" and "model" are terms that deserve careful consideration.

Cast. The Standard Dictionary defines cast, under the heading mechanics, as "A reverse copy, in plaster of Paris or similar material, of a mold; usually distinguished from a *casting*, which is of iron or other metal or alloy. An object founded or run in or as in a mold, as of metal, plaster, wax, etc."

In dentistry, "cast" may be defined as: A reproduction in plaster of Paris or its compounds of an object, or part, made from an impression or mold. Casts are used to give their negative likeness to an artificial denture, while a "model" is to produce a positive likeness.

Model. From Lat. *modus*, measure. An object representing accurately something to be made or already existing. A material pattern of natural, heroic, or diminutive size. In sculpture, the plaster or clay original of a work to be executed in stone or metal. One who does duty as a copy or pattern for painters or sculptors. A sculptor may idealize his living model; but his workmen must exactly copy the model he has made in clay. (Standard Dictionary.)

In dentistry: A plaster model is used to make a metal casting or die. Wax models are to be reproduced, or their outlines retained in the completed work. Models are extensively used in technic work. Plaster models are never used in vulcanite work. "Model" is often improperly used for "cast."

Dental arch. The term applied to the curve made by the upper or lower teeth.

"Arch" is not an appropriate term to be applied to the alinement of the dental armament, because when the teeth are in normal use they are in a horizontal position, while arch conveys the idea of perpendicularity, and is too often applied to the vault of the mouth. The writer would suggest, as a substitute for "dental arch," *dental curve*. A curve is a

line continuously bent so that no portion is straight; a line that everywhere changes its course. In medicine, "curve" is used once—"curve of Carus" (in obstetrics).

Dental curve would be defined thus: The curve or bow formed by the alinement of the teeth. The different portions of the dental curve would be called and described as—

Alinement curve. The line passing through the center of the teeth mesiodistally.

Labial curve. From cuspid to cuspid.

Buccal curve. Buccal surface from the cuspid to the distal surface of the third molar.

Compensating curve. Occlusal surface of bicuspids and molars.

"Curve" would better convey the idea of an imaginary line; when "arch" is used, too often the teeth or even the alveolar process is meant, instead of the line described by the teeth.

Cuspid. This is an anatomical term, but because of its great importance in teaching and practicing prosthesis it seems apropos to discuss it in this place. "Cuspid" is derived from Lat. *cuspis*, point, and is applied to the four conical or pointed teeth. The name is descriptive and not confusing, it is short and not offensive to refined taste. It is certainly the most desirable one of the four names struggling for an existence—cuspid, cuspidati, canine, and eye-tooth. It is true that our standard anatomists cling quite tenaciously to some of the terms of the dark ages, but that is no reason why a modern science should adopt a faulty diction when a better one may be had for the choosing. Many of the schools are today using the term exclusively; it is quite possible that cuspid is more extensively used by the profession today than canine. If the term cuspid be adopted as the name for the third tooth from the median line in the dental armament, then consistency will require that we shall call the eminence and fossa cuspid; but the terms will be self-explanatory, so that no real objection can be urged upon that score.

Dummy. In common use in the den-

tal profession as a name for the substituted teeth in a bridge. The word dummy is not found in the vocabulary of Gould's Medical or Harris' Dental dictionaries, nor is the word given a dental significance in the Standard. As applied it is a meaningless and clumsy term.

At the 1905 meeting of the National Dental Association, Dr. W. Storer How used and indorsed the term *Substitute*, and its abbreviated form "sub," for the teeth filling the span of a bridge. This term is certainly worthy of consideration.

Flasking. In cast-metal dentures the cast and model plate are incased in a flask with a suitable compound; in vulcanite and celluloid work the cast and model plate are incased in a flask with plaster of Paris, and this is called flasking and the work is said to be "flasked." Solder work incased in a protecting substance without a flask is said to be "invested."

Flexible vulcanite. The 1896 committee preferred "flexible vulcanite" to "velum rubber," and defined it as: Vulcanite which is soft and extremely pliable after vulcanization, containing less sulfur than hard vulcanite.

All rubber when perfectly vulcanized is more or less flexible, therefore the term "flexible vulcanite" is confusing. "Velum rubber" before the application of heat, and "velum vulcanite" after the application of heat, leaves no question in the mind of the dentist as to what is meant, and, it seems to the writer, should be accepted as the choice until something better is suggested.

The committee of 1896 included in their definition, "and being vulcanized at a lower temperature than hard rubber." This implies a mistaken idea, as the temperature in vulcanizing either variety should be the same—the thickening of the mass, only, governing the temperature. The velum rubber will require less time to be converted into vulcanite because there is less sulfur to combine with the hydrocarbon; but no harm is done if the velum rubber be subjected to heat the full length of time required for hard vulcanite.

Impression. An imprint of the eden-

tulous ridges and palate, or teeth, in some suitable material, such as beeswax, modeling compound, or plaster of Paris. (Com. 1896.)

A new definition of *impression*: A negative likeness of an object or part taken in a plastic material, from which a cast or positive likeness may be produced.

Impression tray. "Tray" preferred to "cup." "Cup" conveys the idea of symmetry of form with a base on which to stand, and holding capacity; while "tray" conveys the idea of indefinite form, a utensil having flanges, and capacity to hold and carry.

Line. Any slender mark or band.

Median line. An imaginary line on the surface of the body between opposite symmetrical halves. The middle line dividing the teeth. (Black.)

Lip line. The line defined by the lips closed and at rest.

High lip line. The line defined by the upper lip when elevated to the extreme by muscular action.

Low lip line. The line defined by the lower lip when depressed to the extreme by muscular action.

Maxillary. Pertaining to the maxillæ or jaws.

Maxillary surface. The surface of a tray, impression, or artificial denture that rests upon the maxillæ, either upper or lower. (O. A. Weiss.)

Abutment. In mechanics, any relatively immovable part. Dental: The anchor tooth for a bridge. Preferred to "pier" or "anchor."

Abutment crown. The part of a bridge attached to the abutment. Preferred to "anchor" or "pier" crown.

Abutment used as a noun refers to that to which the bridge is attached; the adjective refers to that by which the bridge is attached.

Porcelain (pōrs'-lān). Pottery is divided into three classes—earthenware, stoneware, and porcelain. Porcelain is subdivided into three classes—hard, natural soft, and artificial soft. Dental porcelain belongs to the subdivision *hard* porcelain. Hard porcelain is kaolin and quartz with a feldspathic glaze.

Dental porcelain may be defined as: A

solidified suspension of one or more unfused silicious substances in a fused silicate.

Porcelain is high- or low-fusing, dependent upon the quantity and quality of its basic ingredient. Any hard porcelain becomes glass when there is fusion of all its essential constituents.

Sweat. To send forth, exude, or perspire. Applied in dentistry to the uniting of two pieces of metal by heating and without solder. It is not euphonious, but describes the operation.

Autogenous (au-tog'-en-us). Gk., self-producing. The method of soldering to which this term is applied is brought about by high heat, therefore is not self-producing. This term was preferred by Dr. Guilford in his paper on Nomenclature at the Fourth International Dental Congress.

Weld. To unite or consolidate. This term implies uniting with force, either with or without heat. It should not be used as synonymous with sweating and autogenous soldering.

While the words are not pleasing, the writer believes that "sweat" and "sweating" are the best, because they describe the operation.

Resorption. A term that should be used by the prosthetist, and not "absorption" of the alveolar process. Absorption is best applied to the physiological process of adding nourishment, while resorption best describes the pathological and physiological processes of removing waste tissue.

VOCABULARY.

[St. = Standard Dict. G. = Gould's Medical Dict.]

Absorption. [St., G.] *Absorb*, to drink in or suck up. *Absorption*, the act or process of absorbing; the condition of being absorbed.—*St.*

The process whereby nourishment, medicine, morbid products of tissue metamorphosis, etc., are taken up by the lymphatics and various systems.—*Gould.*

Preference is given to *absorption* for taking up nourishment, and *resorption* for taking up waste products. (See *Resorption.*)

Abutment. [St.] Arch.: A supporting or buttressing structure to sustain lateral

pressure. Mech.: Any relatively immovable part.

The anchorage tooth for a bridge.—*W.* (Preferred to *Pier*, which see.)

Adhesion. [St.] Physics: A molecular force, or the result of it, by which certain bodies stick together.

The force that retains full upper dentures without vacuum chambers.

Air-chamber. [St.] A chamber or inclosed space containing air.

Improperly used for vacuum chamber in artificial dentures.

Alinement (1), *Alignment* (2). [Both forms, Cent. and St.] The line to which adjustment is made.

Orderly arrangement of the teeth.—*W.*

Alloy. [St., G.] A compound or mixture of two or more metals; commonly restricted to compounds of metals produced by heat.—*Com.* 1895.

A compound of two or more materials by fusion. The least valuable of two or more metals that are fused together.—*Gould.*

Anterior. [St., G.] Applied to the six front teeth in either jaw. Preferred to "oral."

Arch. [St.] In dentistry applied to the curve made by the upper or lower teeth. Sometimes wrongly applied to the vault. (See *Curve.*)

Articulate. [St.] To join together.

Articulation. [St.] Any form of a joint; the union forming a joint, as of bones.

Special: To so arrange the artificial teeth as to accommodate the various positions in the mouth, or "anatomical articulation."

Articulator. [St.] A dentist's apparatus to secure correct articulation in artificial teeth. (See *Occlude.*)

Artificer. [St.] One who constructs, especially with skill; a craftsman; mechanic. Artificer preferred to "mechanical man."—*W.*

Artificial crown. A crown of either porcelain or metal, or both; to be adjusted upon the root of a natural tooth.—*Com.* 1896.

Artificial teeth. A dentist's imitation of natural teeth.—*Com.* 1896.

Artificial velum. An appliance composed of flexible vulcanite, used in the mechanical treatment of fissures of the soft palate.

Asbestos. [St.] A fibrous silicate of calcium and magnesium.—*Com.* 1896.

Autogenous. [G.] (Gk., self-producing.—*Gould.*)

Applied in dentistry to uniting metal without solder. Preferred by Dr. Guilford. (See *Weld* and *Sweat.*)

Babbitt metal. Dental formula (Haskell):
Sn 8, Cu 1, Sb 2 parts.

Band. A thin metal hoop used to encircle a natural tooth or root.—*Com.* 1896.

Base metal. [St.] *Com.* 1896. Not of the noble metals. Any metal except Hg, Au, Ag, and the Pt group.—*W.*

Base-plate. That part of an artificial denture which supports the artificial teeth and to which they are attached.—*Com.* 1896.

A foundation next to the gum, for artificial teeth.—*St.*

Bellows. [St.] An implement for creating a blast of air.

Bite. [G.] The act of biting. Seizure with the teeth or mouth. (Anglo-Saxon root meant *split*.) Applied in dentistry to a plastic material which has the imprint of the teeth or gums of both jaws; used in constructing artificial dentures. (Inelegant term.)

Bridge. [G.] *Bridge work*—The adaptation of artificial crowns of teeth to and over spaces made by the loss of natural teeth, by connecting such crowns to natural teeth or roots for anchorage by means of a bridge, and thereby dispensing with plates covering more or less of the roof of the mouth and alveolar ridge.—*Gould.*

A method of dental substitution that does away with the customary base-plate, the artificial teeth spanning the edentulous space with attachments to natural teeth at one or both ends of the space.—*Com.* 1896.

Bridges are "fixed" or "removable."

Bridges are attached to *abutments* by—Bands; crowns; open-faced crowns; bars; inlays; hoods; pin-and-sockets; telescope crowns; lugs.

Bridges are sometimes supported by "abutment saddles."

Bridges are—Porcelain; gold with porcelain facing; all gold.

Caoutchouc. [St.] Indian name for india-rubber. A hydrocarbon. When combined with sulfur and subjected to heat it is converted into vulcanite.

Cap crown. Synonymous with shell crown. Given by *Com.* 1896. It should be dropped from dental nomenclature.—*W.*

Carat. [St.] A twenty-fourth part. *Carat* is the spelling preferred by S., C., E., W., Wr., Imperial, etc., and fifty of the fifty-seven Advisory Committee.

Karat—C., 2d choice; Dr. Butler and Melvil Dewey give it first choice. It seems best to adhere to *carat*.

Carborundum. *Com.* 1896. Carbide of sili-

con, SiC. (Not in Gould's dictionary 1896 or Standard 1899.)

Cast. [St.] (Verb, To shape in a mold; make a cast of.) A reverse copy, in plaster of Paris or similar material, of a mold; usually distinguished from a *casting*, which is of iron or other metal or alloy. The material run into molds at one operation.—*St.*

In dentistry: A reproduction in plaster or its compounds of an object, or part, made from an impression or mold. Casts are used to give their negative likeness to an artificial denture, while a model is used to produce a positive likeness. (See *Model*.)

Celluloid. [St., G.] Made by subjecting gun-cotton (pyroxylin) mixed with camphor to hydraulic pressure. An imitative substitute for ivory. Other names are "Rose pearl," "Zylonite," "Pyroxylin," etc. Sometimes used as a base for artificial dentures.

Clasp. [St., G.] A piece of spring metal, usually platinum gold, adjusted to three sides of a tooth with one or both ends free, and designed to support partial dentures or other apparatus to be worn in the mouth.—*Com.* 1896.

Collar crown. [G.] An artificial tooth-crown mounted upon and attached to a base composed of a metal ferrule and cap, and designed to cover and rest upon a natural root.—*Com.* 1896.

Preferred name for the crown often called the Richmond crown.

Contour. Con-tour—S., C., E., W., Wr., Imp.; con'tour—C., 2d. The line bounding a figure or body.

In prosthesis (verb): To make the normal or natural outlines of a tooth; or to construct a denture so as to restore the normal or natural outline of the contiguous soft tissues.

Corundum. [St.] A very hard native crystalline alumina.

Counter-die. [St.] The reverse image of a die. Usually made of a softer and lower-fusing metal than the die.

Cross-pin teeth. Artificial teeth in which the pins are arranged parallel with the transverse diameter of the teeth. In contradistinction to *straight-pin* teeth. (See *Teeth*—straight-pin.)

Crown. [G.] The exposed portion of a tooth.

Artificial crown: A restoration of the crown of a tooth with porcelain, metal, or a combination of the two.

Crowns are—Porcelain; porcelain jacket;

metal—shell (seamless, sectional, or in two pieces); solid; porcelain-faced.

Crowns are—Collar; dowel; collar and dowel.

Sectional shell crowns consist of—Band (lap or butt joint) and cap—die-and-counter swaged; carved and swaged; die-plate swaged; cast.

Crowns have—Attached or fixed dowels; detached dowels.

(Dowel-pin is the same as dowel.—*St.*)

Curve. [*St.*, *G.*] A line continuously bent so that no portion is straight; a line that everywhere changes its course.

Dental curve. Defined: Curve or bow of the teeth. The different portions of the curve would be called and described thus:

Alinement curve. The line passing through the center of the teeth mesio-distally.

Labial curve. From distal surface of cuspid to distal surface of cuspid.

Buccal curve. From cuspid to distal surface of third molar.

Compensating curve. Occlusal surface of bicuspid and molars.

Die. [*St.*] A facsimile of the form of the mouth in cast metal from which a metal blank is stamped to fit the mouth.—*Com.* 1896.

Die-plate. A metal stamp or die used for forming the cusps on shell crowns.—*Com.* 1896.

Denture. [*St.*, *G.*] The teeth of an animal collectively.

Special: A single set of artificial teeth. Full denture, a double set of artificial teeth, one for each jaw.—*Com.* 1895.

Dowel. [*St.*] Special: A pin or peg (usually of metal) used for joining an artificial crown to the root of a natural tooth.—*Com.* 1896.

Draw-plate. [*St.*] A perforated steel plate with holes of a gradually diminishing size, used to reduce the size of wire and metal tubing.

Dummy. [*St.*] An object made to represent something else externally or superficially.

Special: A tooth in a bridge to supply a missing natural tooth.—*W.* See *Substitute*.

Ferrule. [*St.*, *G.*] A metallic ring or cap applied to the end of the root or crown of a natural tooth to strengthen it.—*Com.* 1896.

A metallic ring or hoop slipping firmly over a natural tooth as a support for a partial denture.—*W.*

Flame. Gaseous matter heated to a state of luminosity.

Flame is—Yellow (carbon heated to in-

candescence) or blue (usually the carbon oxidation is complete, or no carbon is present).

Flame may be—Brush, broad-sheet, or pointed, round-tapering; oxidizing (the end of the flame); deoxidizing or reducing (just in advance of the hollow portion of the flame).

Flask. [*St.*, *G.*] Special: A metal (iron, brass or bronze) rim or box of special design, used to hold the mold for dies, cast and vulcanite work.—*W.*

Flasking. Special: In cast-metal dentures the cast and model plate are incased in a flask with a suitable incasing compound; in vulcanite and celluloid work the cast and model plate are incased in a flask, usually with plaster of Paris; this is called flasking. Solder work incased in a protecting substance without a flask is said to be invested. (See *Invest.*)

Flexible vulcanite. Vulcanite which is soft and extremely pliable after vulcanization, containing less sulfur than hard vulcanite.—*Com.* 1896. The committee preferred "flexible vulcanite" to "velum rubber."

As all hard vulcanite is somewhat flexible, "flexible vulcanite" does not convey a definite idea, therefore is not well named. As "velum rubber" is a definite preparation containing about one-third the amount of sulfur entering into hard vulcanite, and as it is the only variety of soft pliable vulcanite used in dentistry, it seems to the writer that it is preferable to use the term "velum rubber" before the material is subjected to the vulcanizing heat, and "velum vulcanite" after being acted upon by heat.

Flux. [*St.*, *G.*] A material such as borax or alkali, that will dissolve metallic oxides and promote the fusion of metals.

Fusible alloy. Any alloy, but usually one containing bismuth and melting at a very low temperature.

Gage (1), *gauge* (2). An instrument for measuring or indicating capacity, quantity, dimensions, etc.

St. and *Cent.* both give *gage* as first choice.

Gum-teeth. Artificial teeth with a porcelain gum extending above the crown. (Preferred by *Com.* 1896.)

"Section teeth" are block teeth.

Hard solder. [*St.*] Any solder that melts at or above a red heat.

Impression. [*St.*, *G.*] Special: An imprint of the edentulous ridges and palate or teeth in some suitable material, such as beeswax, modeling compound, or plaster of Paris.—*Com.* 1896.

A negative likeness of an object or part taken in a plastic material from which a cast or positive likeness may be produced.—*W.*

Impression tray or *cup*. [St.] A dentist's tray or cup used for holding the impression material while taking an impression of the mouth or teeth.—*Com. 1896.*

Cup conveys the idea of symmetry of form with a base on which to stand, and holding capacity; while *tray* conveys the idea of indefinite form, a utensil having flanges and a capacity to hold and carry. *Tray* is the better term.—*W.*

Ingot. [St.] A mass of molten metal cast in a mold.

Ingot-mold. [St., G.] A flask in which molten metal is cast into blocks or ingots.

Invest. [St., G.] To put a covering upon.

Investing. [St., G.] Participle of *invest*.

Investment. [St.] The material used for covering.

Special: Used in connection with solder work. Where the incasement is in a metal flask (as in vulcanite and cast work) use "flask" or "flasked." (See *Flask*.)

Iridium. [St.] Metal of the platinum group. The hardest metal known.

Iridio-platinum, **Platinum-iridium**. Alloy of the two metals, usually about 10 per cent. iridium to 90 per cent. platinum.

Joint. [St.] The place, point, line, or surface where two or more things are joined together. Joints are either "lap" or "butt." (See *Crown*—sectional.)

Labial. [St., G.] Pertaining to, or toward the lips.—*Black.*

Special: Outer surface of either upper or lower artificial denture, extending from the distal surface of one cuspid to the distal surface of the opposite one.—*W.*

Line. [St.] Any slender mark or band.

Median line. [St.] An imaginary line on the surface of the body between opposite symmetrical halves. (The middle line dividing the teeth.—*Black.*)

Lip line. The line defined by the lips closed and at rest.

High lip line. The line defined by the upper lip when elevated to the extreme by muscular action.

Low lip line. The line defined by the lower lip when depressed to the extreme by muscular action.

Lingual. [St., G.] Situated near or toward the tongue.

Special: The entire surface of either the upper or lower artificial denture next to the tongue.—*W.*

The term *palatine surface* should not be used.—*W.* (See *Maxillary*.)

Long bite teeth. Artificial teeth with the pins considerably removed from the incisal surface, permitting a considerable overlap of the opposing teeth.—*Com. 1896.*

Lower. [St.] Situated below a recognized level. Applied in dentistry to the lower jaw, teeth, lip, artificial denture, etc. Not "inferior."

Maxillary. [St., G.] Pertaining to the maxillæ or jaws.

Special: *Maxillary surface*. The surface of a tray, impression, or artificial denture that rests upon the maxillæ, either upper or lower.—*Weiss.*

Mechanical. [St., G.] Of or pertaining to mechanics on the physical side.

Mechanical dentist. A dentist confining himself to laboratory work. Not an operator, prosthetist, or orthodontist.—*W.*

Mold (preferred to *mould*). (Verb, the act of forming a matrix for a casting.) The form or matrix for shaping anything in a fluid or plastic condition.

Model. [St., G.] (Lat. *modus*, measure.) An object representing accurately something to be made or already existing. A material pattern of natural, heroic, or diminutive size. Sculpture: The plaster or clay original of a work to be executed in stone or metal; a person who does duty as a copy or pattern for painters or sculptors. A sculptor may idealize his living model; but his workman must exactly copy the model he has made in clay.

Special: In dentistry a plaster model is used to make a metal casting or die.

Wax models, which are to be reproduced, or the outlines retained in the complete work. Models are extensively used in technic work. Plaster models are never used in vulcanite work. "Model" is often improperly used for *cast* (which see).

Modeling compound. A material for taking impressions, consisting of a gum (as dammar, cowdie, or copal), stearin, and French chalk.

Moldine. A compound of potter's clay and glycerin used for taking impressions.—*Gorgas.*

Noble metal. [St.] A metal which does not unite with oxygen when exposed to the air or a red heat. (See *Base metal*.)

Obturator. [G.] That which closes a cavity. Dental obturator, an instrument made of metal or hard vulcanite, for an opening in the roof of the mouth. (See *Velum*.)

Occlude. To strike against, or close; as the

upper and lower teeth in a hinge-joint articulator.—*Black*. (See *Articulate*.)

Oxidizing flame. (See *Flame*.)

Periphery. [St., G.] Special: The outer edge of the base-plate of an artificial denture.—*W*.

Pier. [St.] From Gk. *petra*, a rock. It conveys the idea of a built-up mass as a support.

Preference given to *Abutment*.

Plain teeth. Artificial teeth without porcelain gum extension.

Plaster of Paris. [St., G.] Calcined gypsum. Used in making impressions, casts, models, etc.

Plate. A flat, extended, rigid body, as of metal.

Special: The base upon which artificial teeth are mounted.

Plate-teeth. Artificial teeth with headless pins, designed for metal backing and soldering.

Platinized gold. Gold plate covered on one or both sides with platinum.—*Com*. 1896.

Platinous gold. Gold containing a small percentage of platinum, often called "clasp gold."—*Com*. 1896.

Platinous silver. Silver containing a small amount of platinum. In England known as "dental alloy."

Porcelain. [St., G.] (*Porce'-lain*.) Pottery is divided into three classes—earthenware, stoneware, and porcelain. Porcelain is subdivided into three classes—hard, natural soft, and artificial soft. Dental porcelain belongs to the subdivision "hard porcelain." Hard porcelain is kaolin and quartz with a feldspathic glaze.

Dental porcelain may be defined as: A solidified suspension of one or more unfused silicious substances in a fused silicate.—*W*. Porcelain is high- or low-fusing dependent upon the quality and quantity of the basic (alkali) ingredient. Any porcelain becomes glass when there is a fusion of all of its necessary constituents.

Post. [St.] An upright piece of timber, metal, or other material, used as a support. Used synonymously with "dowel," but dowel is the preferred term. (See *Dowel*.)

Prosthesis. [St., G.] (*Pros'-thes-is*, St. and G.; *pros'-the-sis*, *Com*. 1895. From Gk. *pro* or *pros*, and *tithemi*, to place.) The replacing with an artificial substitute a lost part or organ.

Special: The science, art, and esthetics of restoring a lost dental organ or organs and associate parts with an artificial substitute.—*W*.

Prosthodontia. (From two Greek words meaning, "to replace teeth.")

While the word is perfectly formed, it is too restricted in its meaning and conveys a very erroneous and detrimental idea; therefore it should be banished from dental nomenclature.

Reducing flame. [St.] The inner portion of a blow-pipe flame that will reduce metallic oxides or metallic salts to a molten metal button. (See *Flame*.)

Relief. [St.] Special: A space created upon the maxillary surface of an artificial denture to keep it from resting unduly upon the hard tissues.

Removable. (See *Bridge*.)

Resorption. [St., G.] The taking up through the action of absorbent vessels, of tissue already formed.—*St*.

The alveolar process is resorbed, or removed by resorption. (See *Absorption*.)

Retention of artificial dentures. By—Adhesion by contact; atmospheric pressure; clasps; clamps; ferrules; spiral springs; spring plates.

Rubber. [St., G.] A name for unvulcanized caoutchouc.

Ruga and Raphe. [St., G.] *Ruga*, pl. *a*. The lateral folds or ridges in the anterior portion of the vault of the mouth.

Raphe. Applied to the ridge in the median line of the vault of the mouth.

Section or section teeth. [St.] Blocks of one or more teeth with pink gum attachment.

Shell crown. See *Crown*.

Short-bite teeth. Porcelain teeth with pins arranged near the incisal edge of the tooth, which arrangement allows only a short lap over the opposing teeth.

Soft solder. [St.] A solder which melts below a red heat, usually restricted to alloys of tin and lead.

Solder. [St.] A fusible alloy used for joining two metallic substances or surfaces.

Soldering block. [St.] A support for holding the work while soldering.

Soldering flame. [St.] Same as reducing flame.

Soldering iron. [St.] A tool with which soft solder is melted and applied.

Spence compound. A compound of plaster of Paris, Portland cement, and sand. Used for making hard casts for vulcanite, etc.

Splint, dental. Special: An appliance made of metal or vulcanite for supporting either a fractured maxilla or mandible.

Splint, interdental. Special: An appliance made of metal or vulcanite and placed between the jaws to support a fracture of either the maxilla or mandible, or both.

Straight-pin teeth. Artificial teeth with the pins arranged in a line parallel with the long axis of the tooth.—*Com.* 1896.

Substitute. [St., G.] That which takes the place or serves in lieu of another. A term preferred by Dr. W. Storer How to "dummy," in bridge work.

It is a much more expressive and desirable term, and should be adopted by the profession.—*W.*

Suction plate. [St.] (Lat. *sugo*, to suck.) The term is neither euphonious nor well applied. A better term would be *pressure plate*.—*W.*

Surface. The surfaces of an artificial denture are—Labial, buccal, lingual, and maxillary.—*W.*

Swage. [St.] Special: To shape between a die and counter-die.—*Com.* 1895.

Sweat. [St.] To send forth, exude, or perspire. "Sweating" used synonymously with "autogenous." Not euphonious, but best describes the process.—*W.*

Teeth, artificial. Forms or kinds of artificial teeth:

Tube. A tooth having a thin platinum tube occupying the center of its long axis.

Pinless. Having holes and grooves in which vulcanite is attached.

Plate. Having long pins and flat back for solder work.

Facing. Same as *plate*, only thinner.

Saddle-back. Having a concave cervicolingual portion.

Gum. Having a gum-colored portion attached.

Plain. Without gum portion.

Cross-pin. Having pins at right angles to the long axis of the tooth.

Straight-pin. Having pins parallel with the long axis of the tooth.

Slot-and-bar. A removable tooth with a slot in it to slip over a bar.

Bar-and-slot. Having a bar attached to the tooth to slip into a slotted backing.

Short-bite. Having the shoulder and pins near the incisive edge.

Long-bite. Having the shoulder and pins near the middle of the tooth.

Vulcanite. Having short, headed pins.

Vacuum chamber. A space entirely devoid of matter; applied to the depression in a denture calculated to assist in retaining it in place.

Velum rubber. Rubber with about one-fifth of its weight of sulfur. Suitable for making artificial palates. Remains pliable after vulcanization.

Velum vulcanite. Velum rubber after vulcanization.

Vulcanite flask. A sectional metal box for holding an artificial denture while being vulcanized.

Vulcanite. [St., G.] Rubber or caoutchouc that has been compounded with sulfur and subjected to heat.

Vulcanization. [St.] The method of converting rubber into vulcanite.

Wax. [St., G.] Wax is extensively used in the dental laboratory. Pure beeswax, for impressions and articulating models. Wax and paraffin, or earthwax, for trial base-plates, articulating models, etc.

Hard wax, for securely cementing parts in crown and bridge work.

Adhesive wax, which is less brittle and more adhesive than hard wax, is sometimes desired.

Dr. Goslee, "Principles and Practice of Crowning Teeth," gives the following formulæ:

Hard wax. Resin 2 to 4 parts, wax 1 part. **Adhesive wax.** White beeswax 8 oz., pulverized white resin 1½ oz., gum dammar 1½ oz. Melt materials in the order named.

Weld. [St.] To unite or consolidate; as weld to gold in filling. Used synonymously with "autogenous soldering" and "sweating." It should not be so used, as force is the first requisite in welding, and force is not used in autogenous soldering or sweating.

Zylonite. [St., G.] (Same as *Celluloid*.)

A VACANCY IN DENTAL JOURNALISM.

By WILLIAM H. TRUEMAN, D.D.S., Philadelphia, Pa.

(Read before Section I of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

NOTWITHSTANDING that there are many dental journals in the United States, and that their objects and aims cover a wide field, there remains a vacancy. The scientifically inclined are provided with stately journals that fully meet their needs, while readers who desire to be amused find others wherein science, practical suggestions, and jokes—good, bad, and indifferent—are freely commingled. Betwixt and between these extremes we find well-conducted dental journals devoted to special branches of the science; others that appeal, in a measure at least, to the laity, and are intended as much for the waiting-room as for the office. The colleges have their journals, published in the interests of their students. Not one, so far as the writer knows, on this side of the sea, has been especially devoted to the up-building of the dental profession as an organized body. This is the vacancy to which I ask your attention.

That the vacancy exists in this year of grace 1906 indicates an oversight on the part of the profession's leaders.

Organization makes the vast difference in effectiveness between a mob and an army. The dental profession in the United States is a mob. It lacks the inspiration, the discipline, and the unity conferred by a thorough and effective organization. Its many associations interest but a moiety of the profession. They are independent units, each going its own way with but little regard or concern for its fellows. It has no controlling or directing head. It has no mouthpiece. It has no systematic means or methods for reaching its scattered members, or those who newly enter its ranks, to interest them in matters concerning the profes-

sion at large. This aimlessness, this want of organization, subjects its active members to a needless and wasteful duplication of effort in some cases, and leads to working at cross purposes in others. Notwithstanding the many dental journals published in the United States, there is not one to which a practitioner can look for information regarding the profession in his own state, its numbers, its associations, its prospects, or its needs; not one concerned in giving him information on these points regarding the profession at large, its educational institutions, or the legal requirements of the several states. How many can answer offhand. How many dental societies are there in your own state? How many dental practitioners? How many of these are members of a local or of a state society? Where, indeed, let me ask, can this information be obtained? or, when obtained, how can it be made generally known to your fellows? The writer knows of but one publication in the United States that pretends to give information of this kind, or from which it can be gleaned. This is a commercial enterprise, and so expensive that but few can afford a copy.

The result of this is that but few dental practitioners have any knowledge of, or interest in professional societies, and even the members of the societies, as a rule, are satisfied to be interested only in local affairs. Dental practitioners may know, in a perfunctory sort of a way, that there is in their state a state dental society, and that somewhere there is a National Dental Association. Society members may be reminded of their existence once a year, it may be, when the local society goes through the form of electing delegates to these important as-

sociations, or once in the twelve months when they receive a program of the coming meeting. What are their functions, wherein do they differ from the local society, or what are the relations of the local, the state, and the National Association, the one to the other?—who can answer?

A dental practitioner, unless a member of these distant societies or happening to be a subscriber to the journal in which their proceedings are published, may wind up a long and active life in blissful ignorance of their existence. What is to hinder? They make no effort to reach him, nor to interest him in their affairs.

No one will contend, I am persuaded, that this is a desirable state of affairs.

At this time there seems to be an awakening to the evil associated with this, and a desire and an effort to correct it. The question of interchange of state license is bringing to the fore the want of unity between the states regarding professional requirements, and is leading, slowly yet surely, to a universally recognized standard. Some of the state societies, by a vigorous effort, have greatly increased their membership, and their example will no doubt stimulate others to do likewise. There is dissatisfaction with, and a satisfaction within, the National Association and its branches; there is a general feeling that it is not measuring up to its possibilities—and this promises a betterment in the near future. These all are healthy signs.

The dental societies need some means to enable their members to keep in step, to work together, to systematize their efforts and conserve their strength. Furthermore, they need some more effective means than now possessed to reach, bring under their influence, and secure the co-operation of a larger number of dental practitioners. To assist in this the writer suggests the publication by the state societies at frequent and stated intervals, of a journal especially devoted to the interests of the profession in the state—a journal especially designed to bring about a closer fellowship between the state and the local societies. This should give the name, location, executive

officers, the program of each meeting, and now and again the membership list of each local society in the state. In addition to this, such items of information as will tend to keep the state society's progress and needs before the dental practitioners. This might be made sufficiently inexpensive for each issue to be sent regularly to every dental practitioner in the state, and to all others requesting it and willing to pay its cost and postage. This would prove but a slight tax upon the finances of a large state society, while the smaller state societies by uniting could do the same in their bailiwick without embarrassment.

By a similar inexpensive journal, freely distributed to the members of its affiliating societies, the National Dental Association could keep in close touch with the state societies, and through them with the profession at large. The journal of the National Dental Association, in addition to bringing prominently before the profession the state societies, the number of their members, synopses of their proceedings so far as they might be of more than local interest, would of course give prominence to its own affairs. It would invite attention to its own *ad interim* work. The needs of its sections and committees, and the progress made by them, might be helpfully presented from time to time. Its financial statements, laid before the profession in advance of its meetings, would invite confidence and would be suggestive. Changes in the dental laws of the various states, judicial decisions bearing upon them, the more important doings of the National Association of Dental Faculties, of the National Association of Dental Examiners, and of the state examining boards, being matters of general interest, would naturally find a place on its pages, not only in order to give them a wide circulation, but to place them on record where they could readily be found. By confining itself to the business affairs of general interest to the profession; presenting promptly and in a compact and convenient form for preservation and ready reference matters of vital importance

not now published—or if published at all, in so scattered a form among many journals as to render them practically inaccessible—such a journal would have a useful field entirely its own, and would assist materially in building up the business end of professional organizations.

Such a journal need not contain a stated number of pages, but may be contracted or expanded in accordance with the volume of matter in hand. The expense of its publication and distribution can well be met by the National Dental Association without embarrassment. If need be, the addition of advertising pages would offset to some extent its financial burden. It cannot expect, at first at least, any revenue from subscriptions, although the state societies might extend a helping hand. For several years the advisability of the National Dental Association having a journal of its own and publishing its own proceedings has been discussed. The attempt by the association to publish a dental journal in competition with those now in existence is not a promising venture. The association has no experience, is not strong in membership, has no capital, has but little prospect of sufficient financial backing; it cannot command the facilities nor the same careful economic business management as can a well-established, prosperous business house. The

dental profession seems well satisfied with its present professional journals. They have served, and do now well serve as exponents of professional progress in science, in art, and in usefulness. In many of them there is much to commend and but little to object to; they are well managed and keep well to the fore. They are supplied at a cost so close to that of their manufacture that competition in subscription price is out of the question. They are satisfactory to their subscribers, to their contributors, and to a majority of the profession. Until the profession is educated to appreciate sentiment above dollars, yards, and pounds, the dental journals as now published will easily hold their own. The time may come when this may be changed; it is not yet in sight. Until then it is best to avoid an experiment in which failure would not only entail a serious financial loss, but would furthermore prove a disaster by discouraging another effort.

By at first, as it were, "feeling one's way," and at a moderate cost entering a new field—one entirely devoid of competition—with the intention of advancing along lines suggested by experience when increased resources make an advance prudent, there will be less risk of failure; and failure, should it come, will be less conspicuous and less disastrous.

CONTOUR AND OCCLUSION OBTAINED WITH CAST FILLINGS WITHOUT WAXING OR INVESTING.

By A. M. JACKSON, D.D.S., Macon, Ga.

(Clinic presented at the meeting of the National Dental Association, Atlanta, Ga.,
September 18, 1906.)

AFTER securing a good matrix, thicken it with 22-k. gold solder. Then cut a strip of 22-k. or 24-k. gold plate one-sixteenth of an inch wide, and tack the end of the cervical margin

of the matrix by re-flowing the solder. Place the matrix in position on the tooth, and with pliers bend the strip of gold to conform to the outline of the area with which the filling should come in contact.

Burnish the margins of the matrix and remove it from the tooth. The result thus obtained is shown in Fig. 1.

as the soldering was completed, to show how the solder will cling to the outline strip.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

To protect the matrix and to facilitate handling, a bit of investment material is used, as shown in Fig. 2.

The next step is the flowing of the 20-k. solder between the matrix and the outline band until the desired result is obtained, as shown in Fig. 3. One side of the inlay shown at Fig. 3 has been polished, but the other side is shown just

Fig. 4 shows a single contour with the strip in position ready for the soldering. This little strip of gold may be used to contour or raise the cusps of bicuspid or molars by means of cast fillings. A piece of iron wire, secured into the investment material at one end, is of great value as a means of handling during the final soldering.

MANUAL TRAINING AN ESSENTIAL TO DENTAL EDUCATION.

By BURTON LEE THORPE, M.D., D.D.S., St. Louis, Missouri.

(Read before Section II of the National Dental Association, Atlanta, Ga., September 18, 1906.)

IN contending that manual training is a prerequisite to dental education the writer would not discredit or underestimate the skill of the many men who in the past with their mechanical and artistic talent have ornamented dentistry. In reviewing the careers of our foremost practitioners who have made reputations for themselves, it is a notable fact that

the majority, before they became famous as dentists, had enjoyed the benefits of manual training in some form or other, and this doubtless developed the skill which they later exhibited in dentistry.

As many of them were mechanics, who would gainsay that the preliminary training obtained in the occupations of blacksmith, barber, traveling tinker—all hon-

orable vocations—did not make it possible for our professional forefathers to accomplish what they did. For instance, Hayden, whom we may safely denominate the “father of dental science,” was a carpenter and architect; Eleazer Parmly was a printer by trade; W. H. Atkinson and W. W. Allport were both tailors’ apprentices; Elisha Townsend was a watchmaker in his early youth; John Greenwood, a maker of nautical and mathematical instruments; Amos Westcott, an inventor of agricultural implements; Edward Maynard, a blacksmith, civil engineer, and architect, and later one of the world’s greatest inventors; S. P. Hullihen, a silversmith by trade; Marshall H. Webb and W. G. A. Bonwill, inventive prodigies; John J. R. Patrick and N. C. Keep, jewelers and diamond-setters; Elisha Neall, a traveling tinker and clock and watch repairer, while many others followed similar vocations, or obtained a crude manual training in early youth on the farm, which is one of the best schools to give the man self-reliance and manipulative dexterity; for it is a fact that when a man is able to *do things*, both mechanical and artistic, he possesses a degree of self-reliance, self-mastery, judgment, and poise of character obtainable by no other means. Having acquired these qualities, he will have an appreciation for the dignity of labor, and will be able to concentrate his thoughts upon things both mental and material.

Probably the best fruit of manual training is the acquiring of the habit of mechanical analysis, which can be learned only by actual work with tools and materials. In ancient times, “Schools were for the study and mastery of books. The arts of the schoolroom were for masters and freemen, hence they were noble and were called liberal arts. The arts of the mechanics were for serving-men, and were acquired only by intimate association with mechanics; so the practical arts were held to be degrading because of requiring a base companionship.” Criticisms and objections to educational manual training have appeared with less frequency in later years, and the object and value of such training is rapidly be-

ing recognized throughout the civilized world. Men of all ages have recognized the value of skill gained in the use of tools. Time will not permit of our going into an historical *résumé* of manual training, although it is of interest to note that Vulcan, Archimedes, J. J. Rousseau, Peter the Great, our own Emerson, and many others advocated systematic instruction and practice in the details of an occupation. In days past it was taken for granted that the avenue by which mechanical skill could be acquired lay only through apprenticeship. The progress made in educational matters in the past is nowhere more marked than in the teaching of the mechanic arts. Twenty-six years ago the first manual training school in the world—with a course of study “designed to combine manual with mental training; to put the liberal arts and the mechanic arts side by side; to deal simultaneously with material forces and appliances and spiritual forces and appliances; to cultivate the judgment and executive faculties as well as the memory and the understanding; to extend the humanities so as to include human life, human activities, and human needs as they exist now”—was founded in the city of St. Louis, as a department of Washington University, by Prof. C. M. Woodward, who from that time to the present has been at the head of the institution as its director. In this institution, thoroughly equipped with all appliances and apparatus, the student is taught the fundamental principles of mechanics, mathematics, physics, chemistry, metallurgy, electricity, etc. The course of instruction embraces six parallel lines, as follows:

First: A course of mathematics, including algebra, plane and solid geometry, plane trigonometry, and higher algebra.

Second: A course of science, including zoölogy, botany, chemistry, and physics.

Third: An extended course of English language and literature, including grammar, rhetoric, composition, and history.

Fourth: A course in history or a

foreign language, governed by the usual restrictions concerning electives in secondary schools.

Fifth: A course in drawing—free-hand, mechanical, and architectural.

Sixth: A course of tool instruction, including joinery, wood-carving, wood-turning, molding, pattern-making, soldering, forging, and bench and machine work in metals.

When a student has completed this course his hand and brain are both trained to produce exact and artistic results. The element of manual labor enters into the life-work of the dentist more than into any other calling. The underlying fundamentals are mechanics combined with art. The writer has been a close observer of the results of manual training, and has noted that the students who have taken this course prior to studying dentistry make very superior dentists—far surpassing the untutored fellow student in technic work. Personal experience, as in manual training, is the only effective way to train and develop the brain cells which control the movements of the hand, and the value of this method of preliminary education to those who would take up the study of dentistry cannot be overestimated.

It may be contended that the dental student has sufficient manual training in the laboratory courses in our schools. Preliminary educational manual training is not training the hand to turn out

finished products, as in the laboratory, but the training of the brain through the faculties of perception, with elemental studies of beauty, harmony, precision, and accuracy; and although this of course, may result in some finished product, still it is not the hand-produced article, but the impression made upon the mind, that is to be valued. If the student be slow of comprehension, dull, uninterested in the principle of mechanics, unable to see beauty in perfectly executed operations upon wood or other materials, and after careful training is not properly impressed with the value of "accuracy of angle and precision of surface," how can he hope to succeed in the practice of dentistry, which is largely a continuation of these precepts requiring much care and skill in their execution!

The writer fully believes that if a course in manual training were a preliminary requirement to the dental college curriculum, the same as an academic preparatory course is a requirement for entrance to any of our great universities, all dentists of the future would be so thoroughly equipped in technical skill that each would be competent to practice dentistry with a creativeness that would greatly enhance the worth and standing of dentistry.

Dr. Hungerford has aptly said that "Science may quarry the marble, but it is the mechanic, the artisan, that chisels it unto the likeness of a god."

CORRESPONDENCE.

SALOL IN TOOTH-POWDERS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—In the issue of the DENTAL COSMOS for November 1906, page 1165, appears the formula of a tooth-powder which I recommended ten years ago, and which was published at about that time in the chapter on pyorrhea alveolaris of the treatise on "Applied Therapeutics" by Dr. Albert Robin.

A year after prescribing that formula, I observed several cases of eczema of the

lips which I soon traced to the salol in the powder—inasmuch as its elimination from the formula was followed by a disappearance of the eczema. Therefore salol should never be used as an ingredient of tooth-powders, and personally I have discarded it ever since.

Yours truly,

A. C. HUGENSCHMIDT, M.D., D.D.S.
PARIS, FRANCE, March 1907.

PROCEEDINGS OF SOCIETIES.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

Summary of the Proceedings at the Meeting held at Geneva, Switzerland, August 8 and 9, 1906,

AS

Reported by the British Delegates to the Representative Board of the British Dental Association.

TO THE REPRESENTATIVE BOARD, B. D. A.:

We have the honor to submit the following brief report of the proceedings of the meeting of the F. D. I., held at Geneva, Switzerland, August 8 and 9, 1906.

Professor Miller of Berlin presided. Mr. J. Howard Mummery was one of the vice-presidents.

The municipal authorities of Geneva lent the Palais Eynard for the purposes of the meeting, and the city and the state both lent their patronage and support to the Federation.

At the meeting of the Executive Council on the first day, Dr. E. C. Kirk, secretary, presented his annual report. The Council, in pursuance of its policy of non-intervention in strictly national professional affairs, declined the request of the Association of Dental Faculties of the United States to nominate some of its members to a board of regents which should be charged with the consideration of matters concerning professional education in America.

The Odontological Society of Uruguay was admitted to the F. D. I.

An invitation was received from the Dental Convention to be held at Jamestown, Norfolk, Va., in September 1907.

The Treasurer's report and balance-sheet were received and adopted.

A general discussion took place regarding the most profitable sphere of activity for the F. D. I. in the immediate future. In this discussion Messrs. Sauvez, Miller, Paterson, Godon, Grevers, Aguilar, Guye, and Campion took part. As it appeared that there was a demand for a formulated ideal scheme of dental education bearing the imprimatur of the F. D. I., it was remitted to the Commission of Education to draw up such a scheme.

On motion of the British representatives, paragraph 2 of Resolution No. 2, adopted at Hanover, was altered to read—

The reports of the different commissions shall be submitted to the Executive Council. No report shall be regarded as official until it has been adopted by the Executive Council.

The International Commission of Dental Terminology was constituted. For Great Britain the following were nominated: A. Hopewell-Smith, W. Guy, W. B. Paterson, and J. F. Colyer. J. Grevers was appointed chairman of this commission.

To the International Commission of Dental Legislation, G. Cunningham, J. Gaddes, and W. H. Dolamore were nominated.

The principal work, which could never have been carried through unless all concerned had been animated by the greatest enthusiasm and ardor, coupled with a sincere desire for unanimity and mutual accommodation, was the preparation of the reports of the various commissions. It is gratifying to be able to add that in every case the report of a commission, though arrived at only after long debate and earnest discussion, was unanimously adopted by the Executive Council.

These reports follow:

Commission of Dental Hygiene.

Certain questions were submitted to this commission, which formulated these resolutions in response:

(1) It is of the greatest importance for the comfort and health of children, and for the improvement of the standard of physique and beauty, that teachers and scholars in primary schools should receive instruction in the best means of preserving the teeth.

(2) It is of the greatest importance that the teeth of all children, and especially of those between the ages of five and nine years, should be carefully inspected by dental surgeons, and that treatment for the prevention and cure of dental caries should be begun as early in life as possible.

(3) It is of the highest importance that the teeth of children of the poorer classes should be examined and treated by qualified dental surgeons, who should be appointed and paid by the municipality or the state.

(4) The F. D. I. considers that it is part of its duty to bring home to the public the importance of the dentist's professional work.

(5) In addition to public instruction by pamphlet, the F. D. I. considers that this may be best attained by teaching the school children, and providing for them a dental clinic at which they may receive what attention they require. The F. D. I. exhorts the national committees to approach their dental organizations with a view to action in the matter of obtaining municipal or state-aided dental service for the children.

(6) The general meeting of the F. D. I. held at Geneva, August 9, 1906, invites the president of the Executive Council to institute a commission, composed of himself and two other members, charged to prepare a pamphlet instructing the public in the principles of Dental Hygiene, and to this end to procure and consult pamphlets of a like nature which may have already been pub-

lished. The pamphlet to be submitted to the 1907 meeting of the F. D. I.

Mr. F. J. Turnbull of Edinburgh acted as secretary to this commission, his report on what had been done in the matter of Dental Hygiene in Great Britain being very cordially received.

Commission of the International Dental Press.

The Executive Council sanctioned the publication of an *International Dental Bulletin*, primarily devoted to the proceedings of the F. D. I., to be edited by M. Paul Guye, and published in four languages—French, German, Spanish, and English. A subsidy of £40 was voted to the *Bulletin*.

Commission of Dental Legislation.

This commission presented no report, but as a result of its deliberations appointed three subcommittees to consider and report on three separate remits.

Commission to Define a "National Committee" of the F. D. I.

This commission, consisting of Messrs. Harlan, Sauvez, and Guy, presented the following report, which was adopted:

(A)

[See Art. X.]

(B)

I. A National Committee is composed of the representatives to the Executive Council appointed by the permanently organized and duly recognized national dental association of any country affiliated to the F. D. I.

II. Casual vacancies on a national committee shall be filled by its national dental association.

III. The national committee of any country shall be elected by the national dental association of such country, and the election ratified at the annual meeting of the F. D. I.

IV. Appointments to commissions of the F. D. I. of members from any country must be submitted to and assented to by the national committee of such country.

V. Power to take action in any country on any resolution or recommendation of the F. D. I. shall reside solely with the national dental association of that country, which may, however, delegate such power to its national committee.

VI. The F. D. I. Executive Council shall determine the number of representatives to represent a national dental association and constitute the national committee.

VII. In countries where there is no single national dental association, the national committee shall be composed of the representatives of one or more permanently organized dental associations affiliated to the F. D. I. and duly authorized by the F. D. I. to elect representatives.

Commission of Education.

Extraordinary interest was manifested by the members of this commission, and a great discussion took place. Eventually the commission appointed a subcommittee, consisting of Messrs. Brophy, Roy, and Guy, to formulate the report of the commission in a series of resolutions.

The following report, drafted by this subcommittee, became the finding of the commission, and was adopted by the Executive Council:

(1)

RESOLVED, That in the opinion of the F. D. I. measures should be taken to impress on those charged with the general preliminary education of youth the necessity of manual training as the complement of intellectual training, and that this opinion applies with special force to the case of those who are destined to practice surgery or dental surgery.

(2)

RESOLVED, That a committee of five members—namely, Messrs. Brophy (the chairman), Godon, Roy, Guy, and Kirk, with power to add to their number—be appointed to consider formally and submit to the next annual meeting of the Executive Council of the F. D. I. a schedule showing, first, the minimum, secondly, the ideal curriculum of dental instruction, in accordance with the resolutions of previous sessions, to serve as bases on which schools in different countries might build up their qualifying curricula.

(3)

RESOLVED, That in the opinion of the F. D. I. the armies and navies of the world should receive into their services as dental surgeons only men who have completed the prescribed courses in a recognized dental school and have been duly qualified in the country of their service as dental practitioners.

(4)

RESOLVED, That in the opinion of the F. D. I. dental colleges should show in their

time-tables the actual duration in days and hours of their classes and courses of instruction.

(5)

RESOLVED, That a committee, composed of Messrs. Guy, Kirk, and Roy, should be appointed to draw up for the next meeting a report on the means of establishing an International Advisory Board, to study the qualifications and the value of the diplomas in the schools of different countries.

A resolution was also proposed by Dr. Chiavaro to the following effect:

(6)

Inasmuch as the curriculum of dental schools does not impart the instruction, either theoretical or practical, which is indispensable for those designing to engage in the practice of dentistry,

RESOLVED, That in the opinion of the members of the F. D. I. the said curriculum for such persons should be so amended as to provide for instruction extending over a period of two calendar years of not less than 1200 hours each in the special branches of dentistry, and that such instruction should terminate in a legal dental qualification only after a rigid examination in all the branches taught.

There was a French text of this resolution, but it was ordered to be amended in accordance with the English resolution, and the resolution was adopted.

It was decided to hold the next meeting of the F. D. I. at Amsterdam at the beginning of August 1907.

In conclusion, we thank the association for the honor it has done us in electing us as its representatives. We record the great pleasure we have had in taking part in the work of the F. D. I., our conviction that much good will result from the meeting of men representing so many nations, and our hope that many of our members will join the F. D. I. and attend its meetings, thus admitting the existence of and undertaking the burden of international as well as national obligations.

We have the honor to be, etc.,

J. H. MUMMERY,
W. B. PATERSON,
W. HARRISON,
G. CAMPION,
W. GUY.

NATIONAL DENTAL ASSOCIATION.

Tenth Annual Meeting, Atlanta, Ga., September 18-21, 1906.

(Continued.)

SECTION I: Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

(Continued from page 386.)

Chairman—B. L. THORPE, St. Louis, Mo.

Secretary—D. O. M. LECRON, St. Louis, Mo.

THE next order of business was the reading of a paper by Dr. J. Q. BYRAM of Indianapolis, Ind., on "The Present Status of the Porcelain Inlay." Dr. Byram not being present, his paper was read by Dr. George E. Hunt of Indianapolis. [This paper is printed in full at page 433 of the present issue of the *Cosmos*.]

Discussion.

GEO. T. BANZET, Chicago, Ill. My first desire in opening the discussion of Dr. Byram's most excellent paper, is to compliment the essayist upon his noble creation.

However, those who know Dr. Byram, and know of the great amount of work which he has done, both in his practice and experimentally, conducting as he has over three thousand experiments on the fusibility of porcelain, would expect no less able an effort from such an enthusiastic and conscientious scientist. It is a genuine pleasure to discuss this paper, and to endeavor to bring out some points which the essayist has not particularly dwelt upon. I wish to emphatically approve of his position when he states that porcelain should take its place among the other filling materials and not be used exclusively. I have had sufficient experience with porcelain to know absolutely that it cannot be used in all cavities without a great and unwarranted waste of tooth-structure, and no one can practice dentistry conscientiously who confines

himself to porcelain alone as a reparative material.

It is unfortunately true that many are discouraged, some by observation of work which in the beginning was not perfect, and others because they had not perfected themselves before taking up this line of work. The latter condition is particularly deplorable, because it is extremely difficult to convince these individuals that they themselves, rather than the method, are at fault. Experimenting in this work must be done; no one can escape it. The question therefore arises, Shall the experiments be conducted on models outside of the mouth, and where your failures will bring no humiliation; or will you "try it on the dog," and thereby lose perhaps some of your best patients, and your past reputation for skill and progressiveness? Knowledge of the technique and properties of the various porcelains and metals to be employed as matrices, as well as manipulative skill, can be obtained by experimenting on models better than in any other way. It is true that failure of an inlay in contradistinction to that of a metallic filling can be easily determined. Recurrence of decay, which is very rare, can only occur at the margins, and here it is easily discovered and remedied. It is also true that many crowns are inserted when it could be obviated by the use of inlays.

Porcelain is the ideal filling material for all cavities which are not subjected

to masticatory stress, for the reasons which the essayist has advanced, namely, freedom from thermal and electrical action, esthetic appearance, and because of its highly glazed surface, which inhibits to a greater extent than any other material the retention of food débris. For all buccal, lingual, and compound cavities where the margins are not in danger of fracture, as well as for the anterior teeth, I would most heartily recommend it. Cavity preparation must be carefully studied, and for this the work on the models will be the most beneficial.

I wish to take issue with the essayist when he declares that "absolute angles both on the margins and in the cavity are to be avoided." The more nearly absolute are the angles in a cavity, while still permitting the withdrawal of the matrix without distortion, the less will be the liability to dislodgment, the more accurately will the inlay go to its place when set, and the greater the force which it will be possible to use to expel the excess cement. The margins should be almost at right angles to the adjacent tooth-surface, as this form will permit of the use of the great degree of force necessary in order to accurately burnish the matrix, and will obviate the formation of frail margins and friable inlay edges. The vast majority of inlay operators have a horror of getting folds of the matrix on the margin. This, however, is of absolutely no consequence.

Many talk at great length on cavity preparation, and then, in their anxiety to prevent folds on the margin, tear the matrix so badly that they cannot secure perfect adaptation to the walls of the cavity, thus defeating the object of their careful preparation. If the margins have been properly prepared at nearly right angles to the adjacent surfaces, the matrix can be perfectly adapted to the walls of the cavity, and then if folds occur on the margins they can be readily burnished down to the same thickness as the remainder of the matrix without the slightest danger of fracturing the margins; in addition to which the folds will very much stiffen the matrix. I almost invariably use platinum for the matrix, as I

prefer the high-fusing bodies. There is very little danger of distortion in carving or fusing if care be used. I find that a solution of shellac, painted just inside the margins at certain points, will to a great extent obviate distortion in fusing.

I cannot believe that there is greater loss of tooth-structure in preparation for inlays than for fillings. At times there is an apparent loss, but it is always in a position where it will not weaken the tooth. I have many times retained the labial enamel plates of the incisors and canines, reinforcing them with porcelain inlays, where they could not possibly have been safely retained in any other manner. It is essential to be able to carry the tooth-form in the mind, otherwise it will be necessary to place the unfinished inlay in the cavity after each fusing in order to be sure of the proper contour, as all grinding after the inlay is set should be avoided. Water should always be employed to mix the porcelain, and as little as possible, care being taken to absorb all that may remain in the matrix before fusing. This can most easily be accomplished by bringing the porcelain in the matrix into contact with the dry powdered porcelain which you are using, and then removing it with a brush. I have recently been using a foundation body which matches the tooth to be restored as nearly as possible, and then finishing the inlay with the enamel bodies. My usual practice is to employ Whites' bodies—the fusing-point of which is above that of Brewster's foundation bodies—for the foundation, and to finish the inlay with Brewster's enamel and finishing bodies, care being observed not to carry the porcelain to a full glaze except in the last fusing. I prefer hydraulic cement for setting the inlay, as thereby the saliva may be allowed to reach the inlay within two or three minutes, thus conducing much to the comfort of both patient and operator, with the consequent saving of time, as some other operation may be carried on while the cement is crystallizing.

In closing, I wish to indorse what the essayist has to say regarding porcelain art, for unquestionably it is an art to

be able to so restore decayed or broken teeth that the filling or inlay will not be perceptible; and it is only by thorough and conscientious work that one can acquire the knowledge sufficient to secure such results.

Dr. H. H. JOHNSON, Macon, Ga. The paper is a most valuable one, and I think it comes nearer to covering the subject completely than any paper on porcelain inlays I have ever listened to. It shows that the writer is a keen observer, and that he has had vast experience in this work. There are just one or two points on which I would like to speak; one is that he cuts the overlapping margins of the matrix entirely away. I have found that the matrix has greater rigidity and is easier to be kept in shape where the overlap is left quite broad, so that it can be handled with greater carelessness, so to speak, without danger of changing its shape during the process of introducing the porcelain into position.

The allusion to cementing the inlays into place without removing the matrix reminds me of my early experience in porcelain work. In 1893, or about that time, Dr. Downie introduced his little gas furnace, and I made some inlays with it at that time. I cemented these into place without removing the gold matrix, and I do not know whether this was not the reason for these imperfect fillings having lasted as long as they did. I placed several dozens of these fillings in the mouths of patients about that time, and of these I have had four under my observation until last year, when three were removed by Dr. Hinman—one of them being still good—and replaced with much nicer fillings. Of course I believe that at this time I can do more perfect work myself, because we have better materials; but these imperfect fillings did preserve these teeth for twelve years, although the work was imperfectly done, because both the furnace and the porcelain used at the time were imperfect. I simply allude to that because the essayist had something to say on that subject.

He also says that either high-, low-, or medium-fusing bodies will do, according to the preference of the operator. I dif-

fer with him in that respect very materially, as I think that the low-fusing bodies are exceedingly preferable—the lower the better. If I can find any porcelain that will fuse lower than the ones I am now using I will adopt it. I prefer such for the reason that delicate colors are very prone to be changed by heat, and are very easily bleached out. It becomes necessary often to bake an inlay three or four times, and in doing so, the color of the porcelain, especially of the high-fusing one, is continually bleached out. He says, further, that a low degree of heat continued for a long time will not alter the colors. There I differ with him again, for I am aware that a low degree of heat if continued beyond a reasonable length of time does change the color of the body. To succeed, at least in so far as color is concerned, I find that it is necessary to remove the inlay from the furnace just as quickly as possible after the fusing takes place; and I also find when using low-fusing bodies, that it is best to have the furnace heated to the required fusing-point, and when ready, to slip the inlay into the furnace and watch it until the fusing takes place, and then immediately remove it. In this way one is less liable to burn out the color of the porcelain. I have had much greater success since adopting this plan.

The art of making inlays, because it is an art, will probably never be successfully done by the average operator. It is now being used quite generally over the country, probably more generally than the essayist thinks, but there will only be a few, a very few, in the profession who will ever attain anything like perfection in this work. The reason for this is very plain, as a greater knowledge of art is required to mix colors accurately than is called for in any other branch of dentistry. The art of color-mixing also extends to the cement question. You may make a perfect inlay, place it in the tooth temporarily to try it, and probably you will hardly be able to discern it at all. Now mix the cement and place the inlay again in the tooth, and you will find that it is considerably off color. So that one not only has to contend with the color prob-

lem in mixing the porcelains, but also in mixing the cement.

Dr. F. E. ROACH, Chicago, Ill. I do not know that I have much to say on this very excellent and timely paper by Dr. Byram, for the reason that I cannot disagree with him on any point. What I do say will be to further emphasize the good points brought out by the essayist. Knowing him as I do, and the successful work he has done in porcelain, coupled with my own experience and observation, I am prepared to indorse all he has said.

I do not think that there is any question at this time as to the inlay being an established part of dental practice—the inlay in some form. We must accept it as a feature of our practice. While many of us may not adopt porcelain, I feel that there is a field for the inlay method of saving teeth in some of its phases—either the porcelain or some form of gold inlay. We hear occasionally that the popularity of the inlay is on the wane, and that it is soon to be laid on the shelf with other fads. I regret very much to hear Dr. Johnson throw out the discouraging remark that it is only for the few who are skilful—for the man who has the delicacy of touch or the ability to acquire this delicacy of manipulation—to use porcelain as a filling material. I most emphatically disagree with Dr. Johnson in that respect.

Dr. JOHNSON. I did not mean to say that the average operator would not be able to manipulate porcelain successfully so far as making a fit and preserving the teeth are concerned. What I said was in regard to the artistic and esthetic phases of the work, and if I failed to make that point clear it was through oversight.

Dr. ROACH. Dr. Johnson's remark that it requires unusual skill to make porcelain inlays is wrong. I believe that the average operator can acquire the skill to make a tooth-saving porcelain inlay as easily, if not more easily, than he can acquire the ability to insert a tooth-saving gold filling. Experience in teaching porcelain, both to the practitioner and to the student, justifies my belief that the

inlay technique is as easily mastered as that of gold fillings. We do not make perfect inlays every time; neither does the gold operator put in a perfect gold filling every time. And so I say it is wrong to discourage men who are taking up this work. Of course you will have failures, but that does not mean that you do not possess the needed ability. We have not hitherto had the teaching requisite upon the subject of inlay work. It is just in its beginning; we are learning how to make inlays; we are just getting at the first principles. How many will agree on the question of cavity preparation? Some ten years ago Dr. Black gave us a systematized method of cavity preparation for metallic fillings based on scientific principles. We are far from that for inlays, but we are getting together as we are going farther along the line, and eventually we will have a system of cavity preparation; and when we arrive at such a systematized plan there will be no occasion for the claim that men are not able to acquire sufficient skill for making inlays. I have been an enthusiast on this subject for several years and as time goes by I become still more enthusiastic.

I had the temerity two or three years ago, in a paper read before the Northern Indiana Dental Society, to predict that the inlay system would be the method of filling teeth in the future, and I am more strongly of that conviction today than ever. I have never said or believed that gold and amalgam will be laid aside, but I do believe that filling work, in the case of the large majority of cavities that come to us, will in the future be done by some form of inlay. I believe that the man who is not yet practicing the inlay method is doing himself and his patients a great injustice, and the sooner he adopts the inlay method in some of its forms the sooner he will save himself a great deal of hard work, and his patients a great deal of inconvenience; and he will accomplish, I believe, better results.

Now with regard to the fundamental principles of cavity preparation for inlay work. While the difference in cavity preparation for inlays and that for metal fillings is not wide, the principles are

practically the same. We must have free access to the cavity; we must have good solid walls, and if anything we go the gold operator one better in the practice of extension for prevention. For, as the paper says, in proportion as the size of the inlay is increased, its strength will be increased. And so we must learn the very first lesson, and that is cavity preparation. Free access from every angle, sharp margins, slightly diverging walls, and extension for prevention, if you please. Then we come to the rules of retention. The idea has prevailed, and still prevails, that we must depend upon the cement to hold the inlays in position. That I contend has led many men to failure and discouragement. They depend on the adhesion of the cement to retain inlays in shallow cavities. I maintain that all cavities must be so formed that the adhesion of cement will be supplemented by mechanical retention. My opinion is that ninety per cent. of the cavities prepared for inlays may be so shaped that frictional resistance will be the means of retention. Just what I term frictional resistance is this: Take for example the builder's lap in the placing of brick; one brick overlaps one-half of the adjoining brick, so that when the joint between each brick is luted with mortar a very powerful frictional resistance is offered against lateral displacement—that is the form of retention in a majority of inlays. In the case of cavities subjected to considerable strain we must resort to some more positive means of resistance, and that may be accomplished either by pins or by so shaping the cavity that some point or some surface of the tooth will act as a positive plane of resistance in the direction in which the inlay is most likely to be dislodged.

I would call your attention especially to one point brought out in the paper, and that is in regard to the fusing of porcelain. There is no question in my mind at all that Dr. Byram is absolutely correct in the statement that with too many inlay workers there is a tendency to fuse the porcelain too rapidly. The very best inlay will be obtained by

fusing the porcelain at a low heat for a long time. The great number of experiments I have made in my own experience thoroughly and absolutely corroborate this statement, and I want to emphasize this point. The practice I have frequently noticed, of placing a piece of porcelain in the furnace at the maximum heat and attempting to fuse it in a few seconds, is wrong. In that way the porcelain is broiled, and not baked.

There are five factors that enter into the scheme of matching the color of the tooth that one is operating upon, and these five factors are proper fusing, thickness of the layer of porcelain, the underlying colors, the modification of the colors by the cement, and the shadow problem. I find in my teaching of the selection and matching of colors that if I can get the student to bear in mind these five factors the results will be very much better.

There is much more that I might say on the paper, as it is one in which I am deeply interested, but I shall take no more of your time than simply to say that I want you to take it home and digest it—for anything that Dr. Byram writes you can well afford to study at your leisure moments.

Dr. H. L. AMBLER, Cleveland, Ohio. There has been quite a contrast drawn between porcelain inlays and gold fillings by the speaker who presented the porcelain subject, and I wish to contrast the two for just a moment. In 1864, before this association, the statement was made that no preparation of sponge or crystal gold would ever displace gold foil. I desire to make the statement here today that no preparation of porcelain for inlays will ever entirely displace gold foil. I have great respect for those who have developed the electric furnace, and who have spent much time in developing porcelain inlays. I admire the cosmetic effect of such inlays. I have a Custer furnace—the first one invented—and I sometimes make porcelain inlays. Dr. Roach has said that he believed porcelain inlays, in the majority of cases, would displace all other filling materials. It is my opinion, after forty

years in the profession of dentistry, that no young man within the sound of my voice will ever live long enough to see gold, gold and platinum in combination, tin, and amalgam entirely displaced. There are a great many men who can make a porcelain inlay. They can make a matrix fairly well; they can fuse the porcelain fairly well—I do not dispute that—one speaker said so, and I agree with him; but the great trouble with the majority of porcelain workers is that while they often make a fair inlay, when they set it in the cavity it is a failure. I believe we are making too many porcelain inlays today. I practice in Cleveland, which is a fairly large city, and I have seen there some inlays—inserted by operators in larger cities than Cleveland—that came right out of the teeth, and I know that some of these, although they had been made according to correct technique, had to be replaced by gold fillings. When you come to contrast the edge strength of the inlay with that of a gold filling, it is not to be mentioned in the same century. Especially is that true with incisal and occlusal fillings. I want to go on record, as I stated in the first place, as believing that the time will never come when our other good filling materials will be entirely displaced by porcelain. I do not wish you to think that I am decrying porcelain. It is all right in the right place, but it should not be placed in cavities improperly prepared to resist the mechanical forces brought against it.

Dr. ROACH. Dr. Ambler misunderstood me when I said I believed the inlay method would eventually supplant other methods of filling teeth. I did not say porcelain inlays entirely, and I would like to make that modification of my statement. I do not think that porcelain inlays will supplant other filling materials by any means, but I do believe that inlays—the inlay method—will be the most popular method of filling teeth in the future.

Dr. L. E. CUSTER, Dayton, Ohio. I would like to add a few points, one with regard to the idea of quick-fusing porcelain. There has been a demand for quick-fusing porcelain, and we have been

in the habit of trying to fuse it too quickly. That is all wrong, as pointed out in the paper, because during the time of fusing porcelain there is a chemical process going on, and it takes a certain length of time for this to take place, and thus give us a homogeneous mass when completed.

I do not think, as Dr. Ambler seemed to think, that the size of the city has much to do with the perfection of porcelain work. The most beautiful work of this kind I have ever seen had been made by a practitioner in a town of about twenty thousand people.

On motion Section I then adjourned to meet again at a later session.

SECOND DAY—THURSDAY.

The second meeting of Section I was called to order at 9 o'clock Thursday morning, September 20th, by the chairman, Dr. Burton Lee Thorpe.

The first order of business was the reading of a paper by Dr. V. H. JACKSON, New York city, on "Orthodontia: Opening the Bite in the Regulation of Teeth: a Metal Flange for Improving the Anchorage of Appliances, Moving Teeth, and for Harmonizing the Occlusion."

[This paper was printed in full at page 343 of the April issue of the Cosmos.]

Discussion.

Dr. J. W. PEETE, Memphis, Tenn. The paper just read by Dr. Jackson is exceedingly interesting to us as students of orthodontia, and I have few, if any, criticisms to make. He has shown himself a genius, as all who have read his book well know, in devising a great variety of fixtures for correcting the various forms of malocclusion.

Under the first division of the subject, "opening the bite in the regulation of the teeth," the essayist gives us a plan for making a good and efficient fixture. He says it is more commonly used for moving the incisors from lingual to labial position. In relation to these inlocked inci-

sors, it is in my opinion entirely unnecessary. Being a disciple of the Angle system I have always a positive and efficient means at hand that does not need a mechanical fixture to open the bite. There may be cases in which it would be an advantage to open the bite, but I agree with the essayist, they are very few.

Fig. 4 shows unilateral occlusion, entire lack of occlusion of the molars on the right side, lowers to lingual. In this case where there is entire lack of occlusion, and from this cause a condition of supra-occlusion has been induced, I think it would be well to open the bite, as otherwise a long time would be required to move these teeth.

Fig. 7 shows a plate for depressing lower incisors. Here again I must differ with Dr. Jackson. I do not wish to say that he cannot do the work that way, but I believe that there is a better way. I have not been able, thus far, to find a patient who was willing to bite persistently enough on an appliance to depress a tooth or teeth in the sockets. This is, I believe, the most difficult movement I have to make. Therefore I want a fixture that is entirely under my control, and not under that of the patient.

Fig. 14 shows an instrument for expanding the lower arch in the region of the second molars when these teeth are tipped lingually, which, it seems to me, is well adapted to perform the task.

I do not doubt at all that in Dr. Jackson's hands this system is the most satisfactory to him. As every man cannot be as skilful in the use of one kind of gold as he is with another, so it is with different systems of orthodontia.

Dr. W. E. WALKER, New Orleans, La. I have had experience with the Jackson system and also with other appliances for depressing the lower incisors, allowing the molars to rest and extrude at the same time, and therefore I must take issue with the statement of the gentlemen who preceded me, that that cannot be done. Of course he is only expressing an opinion. I believe, however, that Dr. Jackson could say, and I will say, that there is no doubt about it at all.

But coming to the paper itself as to

the Jackson system: As long ago as ten years I gave clinics with it, and have used the system quite a little, and am therefore glad to be able to speak in its behalf, using as I do the best I can derive from the various systems presented to the profession. With reference to opening the bite by soldering a piece of metal over the molars attached to the Jackson crib: In one case I soldered to the metal another piece in the shape of the letter W, on each side of the mouth, which struck just in front of the lower cusps, and carried the lower jaw back and the upper forward in a case of lower protrusion, and it worked very satisfactorily. I might mention for the benefit of those who work with this system, that they will find the electric soldering iron a great advantage, in that it retains the heat while one is working with it.

Dr. W. O. TALBOT, Biloxi, Miss. I have not had sufficient experience with the Jackson system of appliances to speak with authority about any of the forms he has shown tonight, but have used some of them, and I must say with success in a number of cases. In the use of this system I have been impressed with the importance of perfect adaptation of the appliances to the teeth. I also appreciate the points which were brought out by Dr. Jackson in regard to the length of the arms of the appliances. I wish to compliment him on the great amount of skill manifested in the detail of construction of the various appliances that he has devised to produce these movements. In cases where the patients cannot be seen as often as would be necessary were any of the other systems used, these appliances come in very nicely, and I have been using some of them to advantage in such cases. Of the value of the appliances for producing the exact movement that has been shown on the screen I am not prepared to speak, because I really think that in any system of appliances the man who has had experience with them is better prepared to speak than those who merely theorize on them. I think that where we have patients under our control, and can see them often, many of them can be treated

in a shorter time with other systems than the Jackson. I use more of the arch appliances with the clamp bands cemented to the teeth, known as the Angle system, being a student of that system of correcting dental irregularities. I cannot tell in the unfinished cases as shown here whether or not the desired relations for all the teeth were secured. There was one case shown in which Dr. Jackson used the appliance for harmonizing the relation of the arches, and I wish he had shown us the profile view of the cases after completion of the treatment. I hope he has the casts with him, and that we may see them tomorrow. We cannot tell from a front view of the casts whether the mesial relation was established as would be desired.

I do not remember whether Dr. Jackson showed a cast of the finished case of unilateral lingual occlusion.

Dr. JACKSON. I did not.

Dr. TALBOT. I have had some experience in the treatment of these cases, and I have met with good success by using the arch bar, and pitting one whole side of the arch against one tooth on the opposite side, beginning with the most distal malposed tooth, but I have never tried the appliance shown in that class of cases, and therefore cannot speak with any authority on the results obtained in this case.

I wish to thank the essayist for the paper, and to say that I enjoyed it very much.

Dr. W. D. MONROE, Washington, D. C. I do not know of any study that comes before us that is as neglected as this. I have followed Dr. Jackson's work for a good many years, and never miss an opportunity to see his casts and to hear his papers; and as for myself, I think it is the only system that I have ever been able to get anything out of—really the only system that we can call a system.

It is one of the most discouraging things in the world to start to make a Jackson appliance after being accustomed to using hard solder. However, after becoming familiar with the procedure, and following the few points that Dr. Jackson gives us, the appliance can be readily

made, and will go to place as nicely as any appliance you have ever used, and it will stay in position. I think if any man will follow Dr. Jackson's ideas, and apply a little common sense to this work, he will have success, and Dr. Jackson is always ready and willing to give any points regarding the system. As for myself, I cannot say too much for it, and I am only sorry that so few are here tonight to discuss the paper.

Dr. J. A. GORMAN, Asheville, N. C. I enjoyed the demonstration of the making of the appliances, but greatly regret that Dr. Jackson did not exhibit more of the cases completed—showing the final occlusion.

Dr. JACKSON. Occlusion is not the subject under discussion this evening.

Dr. GORMAN. Speaking of driving the teeth down: I really think that instead of driving them down in their sockets and holding them there, we have a tendency to bring the other teeth up, making a happy medium.

Dr. PEETE. Dr. Walker spoke of my saying that it was impossible to produce the results Dr. Jackson has shown with his methods. I do not think I said that, but what I meant was that I believed Dr. Walker, being familiar with the system, can do things with it that others not equally familiar could not possibly accomplish.

Another thing I wish to say: In reference to the spreading of the lower arch in the neighborhood of the molars, I can think of no plan which is more effective than that which consists in the application of the spring wire to the second molar tips when these teeth are only partially erupted. According to my system, it is difficult to place my anchor bands on those molars when they are partially erupted, but with the spring wire I can see that it is perfectly possible. I think there are a great many things in his system that I like, and a great many that I do not, although I may think differently after seeing Dr. Jackson's clinical demonstration.

I do not think, however, that it is easy to depress these teeth by the natural occlusion. We find when the teeth become

tender that the patient will not apply the necessary force, therefore I like to have a force that is under my control.

Dr. JACKSON. Tell us how you do it.

Dr. PEETE. By the application of anchor bands and expansion arch. In the cases where the lower incisors impinge on the gum, there is seemingly a shortness of the molars and bicuspid. Here the question arises, Shall we depress the incisors or raise the molars and bicuspid?

By a careful study of the casts, face, and lips, you will frequently find that one has to have recourse to both procedures.

Having decided thus, I apply the anchor bands to the molars, place the expansion arch in position, and attach to it the anchor bands with wire ligatures or spurred bands and ligatures. In this way I lift the molars, and at the same time depress the incisors with hooks made of thin metal, engaging the incisal edges, or with ligatures, according as to whether I want to move them labially or depress them only. A force is thus produced that is positive and under control of the operator. In the movement of the inlocked incisors by means of the expansion arch with ligatures and screw, in all such cases it is absolute, and only a short time is required to do it, with a minimum of pain and little or no inconvenience to the patient.

Dr. J. ROLLO KNAPP, New Orleans, La. I think we all regret that there are no more present to discuss the paper to which we have listened with so much pleasure this evening. Dr. Jackson is a man, doubtless, of a great deal of skill and ability, particularly in regard to orthodontia, but there are, to my way of thinking, some other very good methods. I was in Chicago a short time ago, and attended a meeting of the largest local dental society in the world. I saw there a great many beautiful casts and some practical cases shown by Dr. Case. I also had the pleasure of visiting Dr. Angle's office in St. Louis, and there I saw about two thousand casts of some very difficult cases that he had carried forward to a successful termination. There is

also a Dr. Knapp—not myself—whose appliances I see advertised in the journals, and he too must accomplish wonders in these directions. It is a pity that there are not some of these men here to discuss this paper, and to answer some of the questions asked by Dr. Jackson. They must do it in some way, I imagine.

Dr. JACKSON (closing the discussion). I am pleased with the discussion of the paper, but I should judge from the remarks of some of the speakers that they have but a very slight knowledge of my system, and of what can be accomplished with it. I am here this evening to show how to open the bite, and how to depress teeth in their alveoli. One of the speakers says that he does not think I can depress teeth in the manner I have described. He has not told us very clearly how he depresses them. The method he gives of adjusting an expansion arch and tying the teeth to it depresses the teeth in some cases and does not in others. The tying of teeth to an expansion bar has proved a most uncertain method.

He speaks of the teeth being made sore by the use of my appliances. The teeth do not get uncomfortably tender if the appliance is managed at all intelligently, and the patient can masticate easily at any stage of the regulation. That is why I claim that this is the "humane system," and up-to-date orthodontia.

I would like to ask Dr. Peete how often he sees his patients each week.

Dr. PEETE. Once or twice.

Dr. JACKSON. I see my patients usually once a week, sometimes once in two or three weeks, the apparatus being removed by the patient for cleansing. Dr. Peete says that my appliances are slower in action than those he uses. Any amount of force desired can be applied. I think after Dr. Peete sees the casts that I am going to exhibit, he will be able to speak more fairly on the subject.

I am showing you a painless method of accomplishing difficult work—work that we have not known how to accomplish painlessly before.

As I have stated, I have been able to reduce the movement of the teeth to practically an exact science. It is impossible

to accomplish this with an expansion bar, as when it is adjusted and additional force is applied to a bicuspid or canine tooth on one side of the arch, the force imparted tends to drag outward some of the teeth of the opposite side of the arch, which in many instances is objectionable. With my system, we have the advantage of using definite anchorage on one side of the arch, and the teeth are not loosened in their sockets in forcing outward one or all of the teeth of the opposite side of the arch.

One of the great advantages I claim for this method is that the regulating is done in definite steps, as the changes can be appreciated each time the case is examined. This is accomplished, as I have described, by making a tracing of the appliance before force is applied, and a dot mark by the side of the tracing of the distance it is desired to change them so as to give the required degree of force. The appliance is then bent to conform to the new marking, and the tracing kept as a record.

Regarding the time employed in the regulation of teeth in special cases, at the demonstration tomorrow I shall present casts showing conditions before and after correction with the apparatus in place. This you seldom see with other methods. I will show how both arches are expanded at the same time with no discomfort to the patient, and I challenge anyone to show as marked expansion of the arch, accomplished with as few visits of the patient.

Dr. TALBOT. Dr. Jackson has asked if those who pay particular attention to occlusion ever show their cases with the apparatus in place. I would like to ask him if he has read the proceedings of the American Society of Orthodontists; if so, he will see there a great many cases shown with the apparatus in place.

Dr. JACKSON. If Dr. Talbot will look over those proceedings and those articles, he will see that they are principally by Angle students, and the same line of thought runs throughout all the articles. I will repeat that you seldom see the apparatus in place on the cast. We see pictures in advertisements, etc., but do

you see the appliance on the cast with the ligatures in place?

Dr. TALBOT. Plenty of them.

Dr. JACKSON. I have shown apparatus which the patient can remove in order to cleanse them, and to cleanse the teeth, there being no excuse for congestion of the gums; and the operator does not have a filthy mouth to contend with—frequently so filthy that he has to wash his hands a second time to deodorize them, and this in the day of prophylaxis. I am showing a system by which one can see and attend to more patients with fewer visits than by any other method of which I know. Remember, gentlemen, that I have been in the field for a considerable number of years, and have tied and twisted ligatures. Only last year, I saw students in colleges twisting ligatures in the mouths of patients for the correction of irregularities, and the tears running down the patients' cheeks. We have nothing of that kind to contend with in my system.

In regard to the application of the method, these appliances have been made by an expert in about thirty-five minutes. How much time is spent in making apparatus and applying it to position with other systems, requiring valuable time that might be given to other patients! I am here to show how to do these things, having no other interest than to help the profession and the patients. I want to thank you for your kind attention.

The next order of business was the reading of a paper by Dr. A. PERCIVAL BURKHART, Buffalo, N. Y., on "Rubber-Dam Method of Abutment Preparation, Interchangeable Facings, and Cementation," as follows:

RUBBER-DAM METHOD OF ABUTMENT PREPARATION, INTERCHANGEABLE FACINGS, AND CEMENTATION.

"Modern crown and bridge work belongs to the department of dentistry formerly termed *mechanical*, but the judgment, skill, and scientific information required place it far above ordinary mechanical dentistry, which has sunk to a

low estate since the introduction of vulcanite."

It can also be said that no branch of dentistry is more abused by avaricious and unscrupulous men, because wilfully they employ it when other means are indicated. Abuse is also shown, as observed by the conscientious dentist, in faulty work and slovenly prepared abutments, and in hideous and disfiguring gold crowns in the anterior portions of the mouths of thousands of patients.

You will observe that bridge work has its dark side, but it also has its bright side, and is a blessing and a comfort to patients when it is honestly recommended and artistically constructed. The interests of the patient should be the guiding principle in all our operations, and a careful examination should plainly and definitely indicate the best system suitable to his case. To arrive at a conclusion, the mechanical portion of the operation is not the only element to be considered; pathology and therapeutics must not be overlooked, if we intend to treat our patients as we would like to be treated, were we to undergo a similar operation.

I shall not attempt to enter into a discussion of the mechanical phase of the subject under consideration, so far as mechanical methods are concerned in the construction of crowns, but shall direct your attention to the preparation of abutments, detachable and interchangeable facings, and cementation.

Close observation for a number of years has convinced me that the preparation of abutments does not receive the average conscientious attention it should, and justifies this conclusion: A dentist who will insert a single crown, or a bridge, upon an inaccurately prepared abutment or abutments, and depend largely upon the cement to keep the crown and bridge in position, is not honest with himself, and certainly has not treated his patient in a manner he would be willing to be treated himself, were he to undergo a similar operation.

Brooklyn bridge, one of the marvels of engineering skill and mechanics of the nineteenth century, and similar struc-

tures which have safely carried millions of humanity from shore to shore, would long since have proved disastrous to life had the same proportionate indifference been shown in the preparation of abutments and piers as is displayed too frequently by many members of the dental profession when approaching and preparing the abutments for a bridge in the mouth of a patient. The bridge in the mouth, as compared with Brooklyn bridge, is infinitesimal, but the underlying and governing principles of construction of the two are alike. Foundation exposure is essential, and truly is this so in the mouth of a patient. And how is this best attained? I answer, By the use of rubber dam held in place by wide-flanged clamps, and sometimes by ligatures; most frequently, however, by clamps. The rubber dam I have thus employed for a number of years, and with pleasing results.

The careful orthodontists obtains accurate casts of the mouth of his patient, so that he may be enabled to study the case under consideration. This rule I also follow in cases requiring medium or large-sized bridges. With the casts articulated I am enabled to devise a safe line of construction from start to finish, and having formulated my plan, I proceed with the preparation of the abutments. After adjusting the rubber dam over a sufficient number of teeth, and extending it over open spaces as quickly and painlessly as possible, I reduce the tooth-substance and accurately prepare the abutment or abutments, unhampered by saliva or secretions of any kind. There are exceptions to all rules, therefore I do not want it to be understood that in every instance I adjust the rubber dam, although I do so in the majority of cases.

In the preparation of the abutments humane treatment should be exercised; therefore, previous to the adjustment of the rubber dam, the gum surrounding the necks of the teeth should be treated with cocain, which will enable the operator to depress the rubber dam painlessly by means of clamps and ligatures, and thus produce an exposure of the necks

of the teeth to a surprising degree. Nowhere in the mouth will the painstaking operator appreciate exposure of tooth-structure more than in cases of forward tipping of molars or bicuspid, especially molars. The use of the rubber dam will be found particularly useful in adjusting the Logan, Davis, Twentieth Century, or any other make of porcelain crowns on the anterior teeth. With the rubber dam in position, I proceed with the reduction of tooth-substance, using the knife-edge carborundum disks made by Lee Smith & Co.

With the sharp-edge disks one can slice down the bulging portions on the anterior and posterior, and labial and lingual surfaces of molars and bicuspid, and this when accomplished will render the tooth almost square shaped. Next, carry the now blunted disks backward and forward over the occlusal surface, thus avoiding long-continued pressure and undue friction at one spot. This variety of disks does away with the violent jarring and friction which the coarse stump wheel produces on the nerves of the patient. Having reduced the sides and occlusal surface, I next complete the final shaping and polishing of the abutment with sand-paper disks. My work is simplified, and the tooth being operated on is kept cool by means of a stream of compressed air directed upon the tooth by an assistant.

In the preparation of abutments, if the teeth are extremely painful, by means of pressure anesthesia I am enabled to shape a tooth to my liking, without causing the patient an undue degree of pain.

Some of my fellow practitioners may consider the use of the rubber dam a waste of time, but they are certainly mistaken, as it means instead a great saving of time. Some may consider it impracticable, but to each I can say, experience is the best teacher. I have had the experience and know whereof I speak, and am sure that if my esteemed fellow practitioners will give the method I have outlined a reasonable trial, they will obtain surprising results.

DETACHABLE AND INTERCHANGEABLE FACINGS.

With the introduction of crown and bridge work, a surprising demand for porcelain teeth or facings arose; but after the lapse of years, the leading tooth-manufacturers have failed to produce anything besides the pin tooth. It is true that better shaped teeth and a greater variety of molds are in existence today than at the time of the introduction of crown and bridge work, but so far as durability and strength are concerned the porcelain is no better at the present time than it was formerly when used for artificial work on gold and silver.

Experience has shown clearly that while the ordinary pin teeth will do for gold and silver plate, they are found deficient in crown and bridge work. After exercising the greatest care with pin facings, the careful operator is always uncertain as to the final outcome. Discolored facings—the result of high heat in soldering—and broken and checked facings confront him, and the conscientious operator becomes sick at heart. It is likely that many within the sound of my voice, after having exercised all the skill and care possible in the construction of a bridge, have been confronted with results such as just pictured, and thus ideal work has not been obtained.

Pin facings have been our great annoyance in the construction of bridges and even single crowns. In the main they are defective when proportion is considered. They are too narrow at the neck, as compared with the breadth of the incisal edge, and as a result, unsightly V-shaped spaces are to be seen between the teeth when a case is completed. These large spaces are particularly unsightly when considerable absorption of gum tissue has taken place, but happily I have been able to avoid this glaring defect by the use of a comparatively new product—a detachable facing.

Pin facings, as stated, are objectionable when the danger of checking and lack of proper proportion are considered. To these faults must also be added

that of change of color due to the high heat essential in soldering. Naturally the question arises, Is there any product which overcomes the defects mentioned? If there is, the facing must be detachable and interchangeable, thus permitting the production of a crown or bridge without subjecting the porcelain to heat at all during the process of soldering; it must be of proper proportions, nearly as wide at the neck as at the incisal edge, and thus with the approximal surfaces nearly parallel the unsightly V-shaped spaces will be avoided.

Ever anxious to take advantage of every mechanical improvement in dentistry, I hailed with delight the Mason facings when they were placed on the market. The product was never fully appreciated by the dental profession. Since the introduction of them, further advances have been made, and notably Steele's interchangeable facings. A little over two years ago I began using the latter, and with satisfactory results. I never worry over checked or discolored facings now. Think for a moment what it means to use a facing of this character! It means a bridge with facings free from checks and discoloration and devoid of large V-shaped spaces, display of gold between facings, and unsightly gold tips. The Steele facings are valuable when a bridge is inserted shortly after extraction, and later, when absorption has taken place, the facings can be replaced with longer ones without the necessity of removing the bridge. Time is saved in the construction of crowns and bridges, and if repairs are needed they can be made easily and quickly. In order to get the best possible results with the Steele facings, the instructions laid down by the manufacturers—chiefly so far as cleanliness of the backings and facings is concerned—must be followed. With each facing comes a metallic backing either of gold or platinum, as the operator may elect. The facings slide on and off easily, and this condition must continue during the whole process of construction.

My early experience was somewhat annoying when constructing an arched

bridge. I found that, after soldering, the facings would bind on the backings, but I overcame this by the following method: After grinding the facing and fitting the backing to it, I remove the latter and invest it, and then I fully back the metallic backing with 20-k. solder. This process I apply to each dummy and then assemble all on the model, leaving for the final soldering only the joints between the backings; requiring little solder, the backings do not warp, and allow the facings to slide on easily. I am convinced that the best results are obtained either with pin or with interchangeable facings, when each crown or dummy is constructed separately, and then all assembled and soldered.

Instead of crystal cement, I now use Evans' gutta-percha cement for attaching the facings to the backings. I prefer gutta-percha because the facing can be removed without injury if subsequent removal should be found necessary.

I have had dentists say, "I prefer pin facings because they are cheaper than the interchangeable ones." The dentist who reasons thus makes a mistake, and the quicker he divests himself of the idea of cheapness of materials when constructing crowns and bridges, the better for him. The ethical dentist should always use the best materials, in order to place himself on a high plane and have the conscious satisfaction of having given his patient the best obtainable, which in turn will justify him in demanding a fee commensurate with his efforts and skill.

CEMENTATION.

While pin facings have been a source of annoyance, misfortunes from another source have come to me: I refer to cementation. The cementation of crowns and bridges has been with me a subject of close study. Many times, for various causes, have I wished for a method to remove easily a crown or a bridge; my desire was not gratified, however, so long as I continued the use of crystal cements. Patients have come to me and said, "Doctor, that bridge you set for me bothers me, as one or more abutments

are sensitive to heat and cold;" or the patient would report a cap loose on an abutment, while the others were perfectly firm. To remove a bridge, as suggested by safety and duty, involved, under such conditions, tremendous labor, mutilation of crowns, and pain to the patient. The conditions mentioned confront nearly every dentist, whether he be of limited or of extensive experience.

Many valuable abutments are destroyed because of the difficulty attending the timely removal of bridges set with crystal cements. For years I have used gutta-percha almost exclusively, and with great satisfaction, in setting single crowns, and about three years ago I began using Evans' gutta-percha cement for setting bridges. At first I used it cautiously, but now I use it almost exclusively. I can quickly and easily remove a crown or bridge now, should occasion require it, and avoid mutilation of the crowns and abutments. I now make it a rule to instruct my patients to return for examination at stated intervals, and if dangerous symptoms present themselves, I remove bridges or crowns and perform such services as will best benefit my patients. Had I used gutta-percha cement earlier in my practice, and observed the rules I do now, I should doubtless have prolonged the life and usefulness of many abutments.

I believe it is good practice, from a sanitary standpoint, to remove bridges from the mouths of our patients at stated periods, and thoroughly cleanse and deodorize them. Fixed bridges, however well and carefully constructed, become foul after a time, and sometimes contaminate the breath.

I am sure the suggestions that I have made regarding my method of abutment preparation, the use of Steele's interchangeable facings, and gutta-percha cement, will be of value if given a fair trial.

Discussion.

Dr. J. D. PATTERSON, Kansas City, Mo. I was very much pleased to hear the paper. I am interested in the Steele facing, and am using it with a great deal

of satisfaction. However perfect our operations may be in using pin facings and in soldering them, there is always, with the most successful as well as with those who are not so successful, a great deal of dissatisfaction because of checking the facing and the difficulty of making a perfect repair without mutilating a bridge or crown. Sometimes the replacing of a facing proves very satisfactory, but often it is not so; and I hail the Steele facing as the best that I have ever tried, and I think I have tried all of the removable facings. The simple objection which I have and of which I have often spoken, is that the backings should be made of platinized gold or platinum-iridium.

Dr. Burkhart spoke of the backings being made either of platinum or gold. They are made of something similar to platinoid. I have entirely discarded those made of so-called platinum and use the gold ones altogether, but I think these backings should be made of iridio-platinum. Sometimes, in forcing these facings on, the barrel is ruined, or melted down in soldering, but if they were made of platinum-iridium they would be much stronger. Aside from this one objection, it is the most satisfactory way of placing facings of which I know.

Dr. N. C. LEONARD, Nashville, Tenn. I am impressed with the need of a better porcelain facing and one that is amenable to our needs. While I am not familiar with the Steele facing, I am prepared to believe that there is quite an advantage in its use.

The only other point to which I wish to refer is the cementation of the bridge with gutta-percha. I appreciate the immense advantage of this method, because of the fact that it is often necessary to remove a piece of work after it has been cemented on, a task difficult to accomplish without mutilating the bridge or crown. I think the essayist is quite right in saying that it is frequently important to remove a piece of work to cleanse it. I have been accustomed to the use of gutta-percha in cementation, but am not familiar with the character of cement that he refers to. I have been in the habit

of filling the contour portion of the crowns with gutta-percha, and then cementing with the ordinary cement, so that when removal is indicated, by warming the bridge slowly the gutta-percha will be softened, when the bridge can be slipped off of the abutments.

Dr. A. J. COTTRELL, Knoxville, Tenn. We are of course very much interested in the remarks of Dr. Burkhart on the use of the interchangeable facings and gutta-percha cement. I think that a cement which permits of the removal of a bridge would be acceptable to any dentist; this is not a debatable subject, it is an accepted fact. But there is one point that I wish to emphasize, namely, the essayist's idea of the application of the golden rule in the making of bridges. I believe that if each dentist, when a patient is in the chair, were to say to himself, "If this were my own mouth and my own bridge, how would I like to have the work done?"—that if we were to apply that reasoning to each and every case our patients would be better served, our reputations would be wider and broader, and our consciences would trouble us less. Gentlemen, do unto others as you would have them do unto you.

Dr. BURKHART (closing the discussion). Dr. J. D. Patterson spoke more particularly about the form of the backing. The Columbus Dental Manufacturing Company, who produce these facings, make three qualities of backings—platinoid, platinum, and gold. I know about the platinoid backing because I used it in my earlier practice, much to my sorrow. With the backings that I have used in recent years—namely, the platinum and gold—I have had no difficulty. Dr. Patterson also said that the manufacturers were open to suggestions. This is true. I made some suggestions recently which the company that manufactures these teeth has under consideration. I am sure that there is not a single dentist who, after once using these facings intelligently, will discard them. While I believe the Steele facings have many advantages over other products, I think that American genius and ingenuity will eventually produce something

which will be still better, but at the present time they are the best we have.

Dr. Cottrell said that we should follow the golden rule in all our work. How frequently are crowns and bridges put in without at all considering the interests of the patient! In the early portion of the paper—and this is a point which was not discussed at all—I spoke of the use of the rubber dam in the preparation of abutments. This is an idea that I have never heard discussed at any meeting, and I have presented it on two occasions. But I can say to you that if you will use the same care that I do, you will not have cause to regret having adopted this method. By this means the tooth around the margin of the neck will be exposed to a degree that will astonish you, and will enable you to accurately shape the abutments.

There is but one other suggestion that I desire to make. I intended to have spoken of it in the paper—the investment of single crowns and bridges. I make a point of saving every box in which sand-paper disks are put up. In these boxes I invest my cases preparatory to soldering, whether it be a single crown or a bridge. In the majority of the boxes a small bridge can be placed. The advantage of this method is that the box acts as a matrix, confines the investment, and does not allow the investment material to spread, as it does, for instance, on a piece of blotting paper, and consequently forces the material close into the joints of the backings and facings. When I invest a bridge I secure a pasteboard box a trifle larger than the bridge, and when the investing material hardens I scrape off the pasteboard and trim the investment if necessary. Save all pasteboard disk boxes; they will be useful.

The next order of business was the reading of a paper by Dr. C. N. THOMPSON of Chicago, Ill., on "Reflected Shadows Accompanying Porcelain Fillings." Dr. Thompson was not present to read his paper, and it was therefore read by Dr. A. H. Peck of Chicago.

[This paper is printed in full at page 438 of the present issue of the Cosmos.]

Discussion.

Dr. L. E. CUSTER, Dayton, Ohio. I think the paper contains many new points on the construction and building up of inlays. It is true that if we at this date possessed a translucent cement, it would overcome the shadow problem to a large extent, but those which have been produced so far are not adhesive, and consequently we have to rely on mechanical anchorage. I believe Dr. Reeves, who introduced the building up of inlays in different colors, has been able to a large extent to overcome the shadow problem, but the essayist in this paper has gone a step or two farther, and has, I think, given us something considerably in advance of the method of Dr. Reeves. He tells us that one of the layers of porcelain should be of a red or pinkish color. How far that will prove to be a good step I do not know, but I believe it is well for all of us to at least give it a fair trial. It seems entirely reasonable as laid down in the paper.

I was especially impressed with the suggestion that we cover the approximal surface of an inlay, where it approximates a metal filling, with white porcelain. I believe there is a good deal of truth in what he says regarding that point.

There is no problem so disappointing to the dentist who is working with inlays as the shadow problem. We feel at this date that we have been very successful in securing these fillings in position, and I think that we should feel thankful to anyone who will aid us in the solution of the shadow problem. For that reason I think we should accept a paper of this kind with great thanks.

The next order of business was the reading of a paper by Dr. L. G. NOEL, Nashville, Tenn., on "Setting Crowns and Bridges with Gutta-percha."

[This paper is printed in full at page 453 of this issue of the COSMOS.]

Discussion.

Dr. A. P. BURKHART, Buffalo, N. Y. As you will probably have noticed in my

paper this morning, I am now and have been for many years very much interested in gutta-percha. The essayist said we knew gutta-percha to be an excellent temporary filling material in the treatment of teeth, and for the retention of a crown placed on a root the condition of which remains uncertain. Now, if it is a good material with which to test a crown for six months, it should be equally as good for permanent use. I have for many years used gutta-percha almost exclusively in setting single crowns. I began by using the plain gutta-percha. I discarded that, however, and began using the Evans gutta-percha cement. I also used S. S. White temporary stopping, and I found, as Dr. Noel stated, that this seemed to harden in the cavity to the density of vulcanite. As far as the preservation of the root is concerned, gutta-percha certainly preserves it better than do ordinary cements.

There are those who use the ordinary gutta-percha for setting crowns, and I think with good results. One method is by coating the pin with a solution of gutta-percha, allowing this to thoroughly evaporate, then filling the root with crystal cement and forcing the pin through the cement. This is a very good method, but in my experience the Evans gutta-percha cement will give still better results. I use gutta-percha for setting bridges in ninety per cent. of all cases, and thereby accomplish results which are highly satisfactory. I can best illustrate by citing a case in practice. I had occasion to remove a bridge—one I had set about a year ago—which rested on four abutments, two molars and two bicuspids. By drying the abutments or caps and then heating them, in a little over eight minutes I removed the bridge without mutilating a single abutment. It is an ideal material for permanent use, one that enables us to remove a bridge easily if occasion requires, and by its use we are benefiting ourselves and our patients.

In discussing the cementation of bridges with gutta-percha, I have heard dentists say "There is danger of burning

the mouth." If you use a little care, there is no difficulty. The great trouble is in being too hasty in trying to set the bridge—there is where the danger of burning the mouth comes in. With the Evans gutta-percha outfit there are two kinds of gutta-percha furnished—pink and white. The pink I use for bridges and the white for single crowns. Now, by carefully heating the bridge on the iron to the proper temperature, the former can be easily placed in the mouth without any danger of burning the tissues.

When you first force a bridge to place with gutta-percha, you will find a little curling up of the excess of gutta-percha around the abutments. Allow the patient to go away, and on his return in a few days, remove the excess. I would not advise cutting this away at the original sitting, but allow the gutta-percha to harden perfectly, for then it may be removed without endangering the portion protruding from the abutments.

Dr. NOEL (closing the discussion). In my efforts to be brief I fear I have sacrificed clearness, and I want to elucidate a few points slightly. I have experimented with the various forms of gutta-percha in solutions, but with most of them like the Evans, I have had trouble in getting the crown or bridge to place. If after laboring assiduously to make a beautiful piece of bridge work we fail to set it properly, we commit thereby a mistake which is very troublesome to correct. It was my desire to get a preparation that would not shrink so much as to allow of the crown coming out too easily, that led me to use zinc oxid. In the setting of a crown or bridge where it may have to be removed one or more times, or in the repairing of a broken facing, the gutta-percha spoken of by Dr. Burkhardt is the ideal material. My idea was not so much to get a permanent material as to devise one that would hold the crown, and not undergo too much shrinkage. To prevent the rapid evaporation of the chloroform I decided to use it in combination with equal parts of eucalyptus. The aristol is used on account of its antiseptic prop-

erties, for I believe it is one of the best antiseptics. Dr. White suggested this idea to me and I have used it with a great deal of satisfaction ever since.

The next order of business was the reading of a paper by Dr. H. H. JOHNSON, Macon, Ga., on "Forcing Eruption: a Case in Practice."

[This paper was printed in full at page 266 of the March issue of the COSMOS.]

Discussion.

Dr. S. H. GUILFORD, Philadelphia, Pa. The operation described and illustrated in the paper was certainly a remarkable one. It is an operation which is not often attempted or successfully performed, but in this case, as shown by the casts, it seems to have been a complete success. It is a different operation, because it is hard to get at the tooth in order to attach the appliance, and it is no easy matter to turn the tooth and to lead it to place. It is also sometimes attended with a great deal of danger. I remember that some years ago a case somewhat similar was presented before the Pennsylvania State Dental Society; the operator succeeded in getting the tooth into place, but after he had done this he found that he had stretched the pulp to such an extent as to devitalize it. I would like to know if anything of that kind happened in this case.

Dr. JOHNSON. No. The pulp is in a healthy condition; but during the operation I found there was some danger from that, and watched it very closely, and when I found the tooth erupting too rapidly, reduced the size of the rubber band so as to decrease the tension on the tooth.

Dr. GUILFORD. Of course, if it happens that the pulp is devitalized, it is not such a serious matter unless allowed to remain too long in that condition. If as soon as the tooth has come to place it is discovered that the pulp has been devitalized, it can be readily removed, and the tooth not be much worse off, unless slight discoloration should result.

I want to congratulate the essayist on

the success of the operation. It is certainly a most commendable thing to bring such a tooth into its normal position and make it useful to the patient. If that had not been done, the other teeth would probably have closed together, with a deformity as the result. In any case of imprisonment of a tooth, an attempt should be made to bring it into place, because if it is not, the arch will be disarranged, and imperfect occlusion of the teeth be the probable result—something that we want to prevent in all cases.

Dr. C. O. KIMBALL, New York, N. Y. This case is especially interesting to me because of the success which Dr. Johnson has met with in treating it. Eight years ago I had occasion to treat a case precisely similar except that the canine was on the right side. The procedure which Dr. Johnson adopted seems to have been a very wise one, and the similarity of the two cases is my reason for speaking now. When the tooth was first located it was lying in almost the same position as the one described by the essayist, with the apex behind the lateral. Its position was discovered only after making an incision of fully one-eighth of an inch under the surface of the gum. It was difficult at that time to set any band on the tooth, or to determine accurately where it was to be placed. So instead of inserting a band—after satisfying myself as far as I could which would be the palatal aspect of the tooth—I made a little pit under the end of the canine on one side of it, and then, with the removable crib of Dr. Jackson's having a hooked wire spring, which curved around over the outer side and under the place where the deciduous canine was taken out—the hook end of this spring was inserted into this pit, arranging the spring so that it could be sprung off to be cleansed and reinserted. In this manner a continuous downward drawing motion was secured. The tooth yielded very readily and came out into line. We then found that the movement was not sufficiently rapid, and therefore adopted the course followed by Dr. Johnson, of inserting a little loop in the end of the tooth, then pulling in the desired

direction to draw it firmly into place. The tooth which has now been in position for seven or eight years is, at the present time, in a normal condition in every respect.

Dr. Johnson's case calls to mind another case which I have to operate upon this fall. It is the case of a young lady one of whose lateral incisors is very crooked and projects considerably over the central. I was at a loss to understand why it had come down in that way, there being no permanent canine on that side. After having had an X ray made I found that the canine was being forced against the root of the lateral incisor. I have been watching the case with the X ray, and we propose to perform the same operation—that is, cutting a retaining point in it and drawing it into position—and we hope for the same success that has attended the operation of our essayist.

The next order of business was the reading of a paper by Dr. W. L. ELLERBECK, Salt Lake City, Utah, on "Comments on General Practice."

Dr. Ellerbeck not being present, the paper was read by Dr. A. J. Cottrell, Knoxville, Tenn.

[This paper is printed in full at page 1179 of the December 1906 issue of the *Cosmos*.]

Discussion.

Dr. A. J. COTTRELL, Knoxville, Tenn. I read the paper with a great deal of interest, and there are a few things I would like to say in regard to it. I, like Dr. Ellerbeck, am very much in doubt about many of the things in dentistry. I detect in his paper the thoughts of one who wishes to remove the hindrance of conflicting ideas and theories, and I, also, would be glad to see the time when some of these theories shall be settled beyond the shadow of a doubt. However, I am not inclined to be pessimistic in this matter, because the theories in regard to dentistry, as in every other great movement—political, educational, religious—are the result of evolution, and no great reform has ever been accomplished at one master-stroke. There are some

things that are settled beyond the shadow of a doubt. The question as to whether the idea of "extension for prevention" is good or not is settled, for me. There is no doubt in my mind, nor in the minds of any of us, I think, as to whether there is a use for the porcelain inlay in dentistry; that is settled. Yet there are some problems that cannot be settled, because the personal equation must enter into their solution.

There is not time to discuss the various points in the paper, but I would like to add just a word. We all like to hit at the colleges and the people interested in them. If we can find no one else to criticize we jump on the colleges. We are all bound to admit that a great many of the students who leave dental colleges are not as thoroughly equipped as they should be for the practice of dentistry—that there is room for improvement. This I admit, and we all know it, but there the question of evolution comes in again. I would ask Dr. Ellerbeck, or any of those people who have a weakness for criticizing the colleges, to compare the dental colleges of today with those of two decades ago. Compare them with those of even ten years ago, and the advance is apparent. Consequently I say I am not pessimistic in regard to our system of education. I admit that it is not complete, but those who make education a study are pressing forward rapidly, and in a most conscientious way—doing the best they can; let us give them a word of commendation once in a while, instead of continually ripping them up.

Dr. WM. CRENSHAW, Atlanta, Ga. I think Dr. Ellerbeck has presented us with a very interesting paper, and one which we shall have to read and study before we can properly appreciate it.

He seems to think, in the preamble of his paper, that the colleges do not improve the rank and file of the profession today. Although I am interested in the teaching of dentistry, I believe that what Dr. Ellerbeck intimates is true to a greater extent than the profession realizes.

I believe there is an opportunity in

what he suggests as to the feasibility of a commission to settle certain mooted methods of practice. In some schools we find, for example, that they are teaching exclusively the manipulation of cohesive gold, as they consider it the best form of that filling material for saving teeth; while in others the use of soft or non-cohesive gold is advocated as the only correct thing. These methods are so far apart as to results that nothing but confusion in the minds of the students comes of it. Again, for illustration, if each of the physiologists of today were to present as proper teaching for students in medicine and dentistry his own opinion of the circulation of the blood, digestion, and assimilation of food, we would have as many opinions as we have teachers—but they do not do that. These matters are settled by the authorities on the subjects, and although you might employ a half-dozen physiologists, you will find that they all agree with regard to circulation, digestion, and assimilation. Now, when these things are settled, you can teach something definite, because there is a basis to work on. It needs to be as the law in our courts, under which the lawyers work, which comes from a settled ruling—a head and authority. I regard the suggestion as a good one—good for our profession, and of course for the public at large.

Dr. Ellerbeck states in his paper that cavity preparation on scientific lines is taught by Black, Johnson, Kirk, and others, giving credit for the present prevailing methods of preparation of cavities. These gentlemen have done their part, to be sure, but they have not originated what they are teaching, and it fatigues me somewhat to see this honor constantly misapplied, and the credit of it given to men who have not originated it; for the credit and the very soul of this extension for prevention, and about every feature of cavity preparation worth adopting, is due to Dr. Marshall H. Webb. He did not call his system extension for prevention, but that is what he taught, and the re-vamping of his teaching does not change or improve its principle. Some small modification may have been

made of some parts of his work, but Webb is the author of the system, and he should have the credit. I think the commission as contemplated by the essayist would find Webb's work settled, so that, as from the rulings of the Supreme Court, there can be no appeal.

He refers in his paper to the phenomenally rapid operator, and to the phenomenally slow one, instancing the man who prepares a cavity one day, fills it the next, and finishes the filling the third, taking three days to fill the tooth. Now this is ridiculous, and yet there are some operators who make themselves just as ridiculous by operating too rapidly. I have known operators to knock fillings out before finishing them, because of working too fast. Dr. Atkinson, great man that he was, once did this at a clinic. Conservatism will prevent us from working too fast or too slow. More than most specialists, the dentist must give the proper time and attention to his work, or it must inevitably prove a failure.

I think the essayist is rather over-alarmed at the deleterious effects of the dust arising from the excavation of teeth—dust which he intimates lodges in the cells of the lungs of the operator. I judge others by myself, and try to dodge this dust, and give it to the patient, to whom it belongs. Fortunately it is only occasionally that we are exposed to this.

The suggestion of the use of the matrix in guarding against the cutting of the gum is a new idea, and I think a valuable one in the preparation of the gingival surfaces of molars and bicus-pids, or at the cervical border of the cavity. This and other valuable thoughts are constantly occurring throughout Dr. Ellerbeck's paper.

With regard to the use of the particular tin cylinders referred to by the essayist, I do not think it good taste to say it, but for history's sake will state that I am the originator of these cylinders. Both the manufacturer, Edward Rowan, and Dr. W. D. Tracy, to whom our essayist refers, will confirm this statement. The difference in these cylinders and those made formerly by Rowan, is that the cylinders I suggested are made of

corrugated tin foil. These are softer and more readily adapted to the tooth-structure in connection with any matrix you may choose to employ.

The last thought I shall notice is the condensation of gold. But I shall not attempt to say anything on that portion of the paper dealing with the manufacture of porcelain inlays, bridges, crowns, etc., because these are out of my line of work, and I do not feel I could add anything of value.

In regard to the condensation of gold, I think that there is a limit to it, and that it is entirely possible to over-condense the material. This is more true of the soft than of cohesive gold, and yet I am convinced that over-condensation of cohesive gold destroys the usefulness of the fillings, particularly after leaving the margins, in a larger measure than we are aware.

Dentists of less experience than mine, and particularly those of more, will testify that with reference to soft-gold work, they have extracted teeth that had been filled by such men as Maynard, the Badger brothers, Emerson, and others. These practitioners filled teeth with various preparations of soft gold, and by methods that were not much more than stuffing the teeth, and yet they have been preserved for forty and fifty years.

Dr. A. P. BURKHART, Buffalo, N. Y. I would like to say a few words, and those few words are the outcome of the remarks made by Dr. Crenshaw relative to the filling of teeth in which soft foil may be used. He has well said that many of the fillings placed in many years ago, which can be almost picked out, have preserved the teeth for years. I have in my own mouth fillings that were inserted thirty years ago, in which the gold was put in by hand pressure, and they are doing good service today. I want to say in this connection that in filling, my greatest effort is to exercise pressure against the walls of the tooth. I think a filling of soft foil firmly laid against the walls of a cavity will preserve a tooth longer than an over-malleted filling would. I believe one of the greatest faults of the young men of the profession today is the over-

malleting of fillings. The fillings described by Dr. Crenshaw and the methods employed by him and others will produce the best and most lasting results.

The following was read by title, the time for adjournment having arrived:

Paper by Dr. E. PARMLY BROWN, New York, "The Inevitable Outcome of Crown and Bridge Work."

The chairman, Dr. Burton Lee Thorpe, then declared Section I adjourned *sine die*.

SECTION II: Operative Dentistry, Nomenclature, Literature, Dental Education, and Allied Subjects.

Chairman—H. E. ROBERTS, Philadelphia, Pa.

Secretary—C. S. BUTLER, Buffalo, N. Y.

FIRST DAY—TUESDAY.

THE first meeting of Section II was called to order at 8.30 o'clock Tuesday night, September 18th, by the vice-chairman, Dr. W. R. Clack, Clear Lake, Iowa.

Dr. Butler announced that the chairman of the section was prevented from attending the meeting on account of having all his funds tied up in the bank which failed in Philadelphia recently, and moved that the vice-chairman of the section be instructed to send a telegram of sympathy to Dr. Roberts, and the regrets of the section at his inability to be present.

The motion was carried.

The first order of business was the reading of a paper by Dr. CHARLES McMANUS, Hartford, Conn., on "The Remarkable History of the Profession and the Splendid Character of the Men of the Past who Helped to Build It Up"—being the report of the Committee on History—as follows:

THE REMARKABLE HISTORY OF THE PROFESSION, AND THE SPLENDID CHARACTER OF THE MEN OF THE PAST WHO HELPED TO BUILD IT UP.

I assure you that it requires a certain kind of courage—to call it by no harsher term—to present an historical paper before a meeting of this character. It would seem little less than cruel to take a body of practical dentists, whose thoughts are on the future of their pro-

fession, and force them to consider the state of that calling, if not a thousand, at least hundreds of years ago.

My good friend Dr. Wedelstaedt* has said, "Let us rather work for the future of our profession, its advancement and progress, than to be forever dwelling upon its past history." I thoroughly agree with him, and yet—well, the traditions of the dental art are so interesting, and the men who in all countries and all ages have worked to make modern dentistry possible are so worthy of remembrance that it seems as if every one of the young men, or women, who propose to devote their life to and receive their livelihood from dentistry should at some period of their career be given a chance to study the subject.

In the first report of your Committee on History, made seven years ago it was stated that "In the opinion of your committee it would be well for the future culture of the dental profession if no class were allowed to graduate from any college without receiving the benefit of a short course of lectures on the subject."

So I ask you this evening to listen patiently to what I have to say, to look at the illustrations (which are more human documents than pictures) not as if they were addressed to you, for to some of those present it is a familiar story, but as if they were being offered to the young man beginning the study of his profession.

* Trans. St. Louis Congress, vol. iii, p. 26.

I shall touch very briefly on our history previous to the time of the great Fauchard, the "father of dental surgery," whose career is so inspiring and the man so worthy of our affectionate remembrance. It will be unnecessary for me to more than mention the early pioneers in America, as their lives and portraits have been presented to you in the journals by Dr. Thorpe, as well as in a paper read by him at your last meeting in Buffalo.

In the limited time at my disposal I can only hope to suggest to you the possibilities of the subject, attempting in an hour to sketch to you what in some detail would require at least three or four lectures. I have selected, out of a collection of several hundreds, about fifty lantern slides of instruments and appliances as well as portraits which add vastly to the interest of the subject when presented before the average dental student. It is the belief of the speaker that, when we can properly impress the lesson of the remarkable history of dentistry and tell of the splendid men who, in all countries, have helped to found and maintain it, it cannot help but have a practical *ethical* value in building up the professional character and self-respect of the young students upon whom dentistry will largely have to depend for its future professional standing.

The speaker then traced the history of the dental art from the earliest records we have of dental medicine given in the papyrus of Ebers, which reaches back as far as 3700 years before Christ, calling particular attention to the various erroneous assertions regarding artificial teeth, and particularly gold fillings said to have been found in the Egyptian mummies, which are *as yet* entirely devoid of foundation. Slides were shown of Phœnician and Etruscan work, and mention was made of the early Greek and Roman writers upon the subject, with illustrations of the various implements and appliances of the time.

Passing on to the middle ages, the Arabians—Rhazes, the initiator of the operation of filling teeth, and Abulcasis (eleventh century), the originator of a

systematic prophylaxis—were given due attention. The first complete set of scalers, those of this pious and persistent prophet of prophylaxis, were shown on the screen.

Attention was then called to Giovanni d'Arcoli, who in 1450 was the first to put on record the use of gold for filling teeth, and a brief account given of Ambroise Paré, who has been styled "the foster-father of dental surgery." A rare portrait of Dr. Nathaniel Highmore was shown, as well as one of Van Leeuwenhoek.

Passing on to the eighteenth century, instruments from the work of Pierre Dionis were shown.

Attention was now particularly called to the great dentist Pierre Fauchard, "the father of dental surgery," whose life and works were described and illustrated. Little is known of the early life of this illustrious man, and the exact date of his birth is still a matter of dispute. A disciple of Poteleret, surgeon-in-chief to the king's ships, his early attention was directed to diseases of the mouth and teeth. Viau, an authority on the subject, says that he had tried several mechanical professions, and the knowledge of these was undoubtedly of value to him later in his career. He determined, after practicing in various towns, to test his success on a larger scale, and in 1719 went to Paris, where at this date, and even earlier, there were not only "tooth-pullers" on the Pont Neuf, but also dentists properly so called. Of one of the latter, Monsieur Carmeline, Fauchard speaks as an able and celebrated surgeon-dentist. In 1728 appeared Fauchard's great work "The Surgeon Dentist," in two volumes, with over forty full-page illustrations, a number of which were described and shown on the screen. This book was translated into German and published in Berlin in 1733; a second edition appeared in Paris in 1746, and a third appeared, after the author's death, in 1786. It has never been translated into English, which is much to be regretted. Following the usual custom of the time the work begins with a fine portrait of the author.

This is interesting for two reasons, the first being that Fauchard is shown to us as a person of distinguished appearance, and this gives us a hint as to the social condition of the better class of dentists in Paris during the reign of Louis XV; and second, because of the Latin verses annexed to the portrait, which Dr. Wm. H. Trueman has cleverly put into English rhyme as follows:

Whilst Fauchard with wise hand and pen
For health and beauty of the teeth contends,
Envy's mad tooth is gnashed in vain;
His noble nature treats it with disdain.

It is the pitiful little human touch which shows us that this man, the grateful friend of the famous Carméline, the friend and dentist of many of the members of the College of Surgery and Faculty of Medicine, had among his own *confrères* a few spiteful and envious detractors. This caused Fauchard in his second edition to state that—

The rumor having been falsely set about that he has abandoned the profession, which rumor cannot have been invented otherwise than by those individuals who, sacrificing honor to interest, would attract to themselves the persons who honor the author with their confidence; he therefore finds it necessary to give warning that he still continues the practice of his art in Paris, in the Rue de la Comédie Française, together with his brother-in-law and sole disciple, M. Duchemin.

Or the Latin verses may, perhaps, refer to the bitter controversy that Croissant de Garengéot—a studious, dull man who is remembered for the key he *didn't* invent—carried on against him.

Space will not permit taking up in detail many of the points in his book referred to. Some of them are very curious. Fauchard did not approve of tooth-brushes, and advises the use of small sponges in their stead. He preferred tin to lead for filling teeth, and did not care much for gold. "Besides," says he, "gold being dear, not everyone can, or will, make the corresponding outlay."

Fauchard has much to say of interest in the chapter in which he treats of the

correction of the irregularities of the teeth. He made use of the most simple means, the file, pressure with the fingers, common or silk threads, and little plates of silver and gold. At times for straightening teeth he made use of the pelican and straight forceps, afterward tying the teeth in the normal position. He rarely had recourse to extraction as a means of carrying out dental correction. (Fauchard, vol. ii, p. 87.)

In closing the account of Fauchard the speaker said: "Before leaving this mighty man, I wish to put on record my sincere belief that the day will yet come when some public recognition of the obligation we are under to this great Frenchman will be made, and that a statue of him will be erected in the city of Paris by the grateful contributions of the dentists of America."

After speaking of some of the followers of Fauchard, the history of dentistry in England was taken up. Passing to the first records of the art in our own country, many advertisements of the first practitioners were shown, and the usual account, with portraits, given of Lemaire, Gardette, Flagg, the Greenwoods, Koecker, Hudson, and others. The early history of the profession, the founding of the society, the journal, and the college, was referred to, and a brief account given of Hayden and Harris. Particular mention was made of the many distinguished dentists of the South, and their portraits were shown on the screen.

In closing, the essayist spoke of the History of Dentistry, by Dr. V. Guerini of Naples, which is now in the hands of the committee, as follows:

This wonderful work is ready for immediate publication as soon as seven hundred dentists out of the 30,000 practitioners in this country evince enough interest in the subject to signify their desire to subscribe to it. Your committee has sent out thousands of circulars to the most progressive dentists in the world; the matter has been widely published in the dental journals, in many cases with editorials, and after many months but about 400 subscriptions have been re-

ceived. We require at least 300 more to begin the publication of the book. There is no time to lose; this remarkable record of the early history of the dental art must be presented before the record of American dentistry can be properly considered. Is it too much to ask your earnest co-operation with us in this great work?

Discussion.

Dr. J. Y. CRAWFORD, Nashville, Tenn. It affords me a great deal of pleasure to be called upon to say something in commendation of such an exquisite work, from an historical standpoint, as has been exhibited to us this evening. I would not presume to add anything to the splendid presentation that we have had. It has always afforded me great pleasure to listen to Dr. McManus in the presentation of anything that he has done for dental surgery; and I feel sure that the work he is doing will, one of these days, place his portrait upon the screen to be looked upon by our successors with as much pleasure and pride as we have looked upon the faces that he has exhibited to us tonight. The dental profession is under great obligation to Dr. McManus for this work, for of all the work in the world of a literary character, I have always believed that of the great historian was perhaps submitted to the severest test. All peoples pass upon the merits of the work of the historian—a work that has very much to do with the formation of public sentiment and in placing that estimate upon character that character is entitled to.

I feel that everyone present tonight is giving to this paper that high appreciation which it deserves, and if the spirits of the souls of the departed watch over and take an interest in the affairs of men, what must be the pleasure of those that have been represented upon the screen tonight, when they look down upon this consecrated scene in this southern city, and hear what the essayist has said in honor of their memory! May the essayist continue in his work to create in the hearts of the dental profession of the world a permanent shrine for the mem-

ory of these men who have lived so cleanly, and who have done so much to benefit humanity in the past. May all of this be, to the young men who come after us, an inspiration to still higher attainments in the work of our beloved dental profession.

Dr. BURTON LEE THORPE, St. Louis, Mo. I want to say just a word in appreciation of the immense amount of work done and the time which Dr. McManus has spent in gathering this and other data in his possession. I dare say you all realize that he has shown you on the screen only a few pictures of the many in his collection. He has also told you only a few scattered facts regarding the careers of the men whose faces he has shown tonight. They are the men who have made dentistry, not only in America but throughout the world, and to them, professionally speaking, we owe everything that we have in the way of high standing and character as a liberal and respected profession.

I imagine that none of you can quite realize the immense amount of work, time, and money that Dr. McManus has spent in gathering these data. I have done some work along this line, and I assure you that it is a labor of love, and it is to the credit of Dr. McManus that he is willing to work for the honor and the glory of his profession in giving us something in a permanent shape, which we can record as the absolute authentic history of dentistry. No other profession has so little history to its credit as dentistry. We have been negligent in the past and it is only within recent years that we have been able to obtain these historical data in a permanent form, and therefore I can heartily indorse the recommendation made by Dr. McManus, that this association should take it upon itself to do the right and appropriate thing by subscribing to Dr. Guerini's history of ancient dentistry—a most remarkable work done by a most remarkable man, who has had the energy and enthusiasm to devote his time and labor to the gathering of these data, in order to give us an authentic record of the true status of dentistry in the ancient times.

No one in the world, to my knowledge, is as happily situated as Dr. Guerini for carrying on this work, living as he does in Naples, the fountain-head of historic lore, where he is surrounded by ancient tombs, museums, and libraries, in which he can collect these facts from the molding and decaying records of ancient dentistry. I hope that our members have the love of the profession at heart, so that everyone will contribute five dollars—which is the price of the subscription—toward the publication of this book under the auspices of this association.

Dr. H. L. AMBLER, Cleveland, Ohio. Personally I wish to thank Dr. McManus for presenting this paper, and I think we should all feel that we have learned a great deal this evening, because I know very well there are very few dentists that have ever made any study of the history of the profession. Dr. McManus, and also Dr. Thorpe last year at Buffalo, showed before this association many pictures of pioneer dentists, and told us many interesting things about them, and they should have our thanks, not only for collecting these numerous pictures, but also for gathering the biographical sketches of those whose pictures were exhibited. I have done very little compared to what Drs. Thorpe and McManus have accomplished in this direction, but I can very fully appreciate their work, and can assure you that no one in this room who has not attempted such work can imagine the amount of correspondence, the number of personal interviews, and the traveling expenses involved in it, and for that reason I think these men should have our thanks.

I will simply refer for a moment to one other point of which Dr. McManus spoke, and which was not noticed by any of the other speakers, viz, that every dental college should teach more or less of dental history to its students. I am very fully in accord with that idea, as it is the most appropriate thing in the world to teach students what the pioneers in their profession did. Now, it is plainly evident that it is an easy thing to interest people and to interest students in the study of history. When you can have

a picture placed before them, and a biographical sketch read to them, history becomes the easiest subject in the dental curriculum in which to interest students, and every lecturer upon the subject will tell you the same thing. As you are not students here this evening, I will carry the illustration one step farther, and say that this fact is very well demonstrated here, because the attendance this evening is the largest that we have had at any one of our meetings thus far.

The credit of first introducing the study of dental history into the dental college curriculum is due to a gentleman who is present here tonight. The first man to be appointed a professor of dental history is Dr. Cigrand of Chicago. In or about the year 1892 he began to give a course of lectures to the students at the college with which he is connected, and your speaker is the second one who ever took up the subject and gave a course of lectures in a dental college; this was at the Western Reserve University dental department, and since that time I have kept a record of the dental colleges which have paid more or less attention to this subject, and at present there are nine out of about fifty which are teaching dental history, a fact showing that the subject is gaining a hold not only upon the profession but also upon the students, and through them upon the laity. And what is more appropriate than that the dental student should know something of the history of his profession? What profession can you name that teaches its students nothing concerning its founders and pioneers? You cannot name a single profession—law, art, literature—that does not teach its students something about its history. Now, is it not high time that all the dental colleges should wake up to this fact, and teach their students something of dental history in order to place us on a level with the other professions in that respect? We want to be placed on a higher plane; we want to be on a plane with theology, law, and medicine. If we do, then is not the teaching of history a step in that direction?

Dr. McMANUS (closing the discussion). I just want to say that this work

has not been the labor of any one man, but of a great many, and none have done better work than Dr. Thorpe in publishing in the dental journals the biographies of our early American practitioners.

I was glad that Dr. Ambler spoke of Dr. Cigrand, who is a pioneer in this study; I also think we will all agree that one of the greatest men in connection with historical work in dentistry is Dr. Wm. H. Trueman of Philadelphia. He is the leader of us all, and when we are in doubt and want to know the facts we go to Dr. Trueman. Dr. Kirk, notwithstanding his many other duties, is also very much interested in this work.

In France they have a history of dentistry by Lemerle, and one in Germany by Geist-Jacobi, but there is nothing accessible in English, and that is what we are working for and will have very soon, if the dentists of this country support the effort now being made to publish Guerini's history. I would be ungrateful if I did not express my appreciation of the kind remarks made this evening, even though I cannot quite agree with all of them.

Section II then adjourned until a later session.

SECOND DAY—THURSDAY.

The second meeting of Section II was called to order Thursday, September 20th, at 12.30 P.M., by the vice-chairman, Dr. W. R. Clack, Clear Lake, Iowa.

The first order of business was the reading of a paper by Dr. GEORGE H. WILSON, Cleveland, Ohio, on "Prosthetic Nomenclature."

[This paper is printed in full at page 456 of the present issue of the COSMOS.]

Discussion.

Dr. S. H. GUILFORD, Philadelphia, Pa. I think this organization is to be congratulated on having secured a paper such as the one we have just listened to. I feel sure that it will be considered one of the best papers presented at this meeting. I do not know of anyone better fit-

ted to write upon this subject than Dr. Wilson. As many of you know, Dr. Wilson is not only a student, a teacher and writer, but he is also a worker. I take a very deep interest in this subject and have for many years, and the reason why I do so is because I love my profession and want to see it rise to a higher plane. That can be done in various ways, and certainly this is one of them. We are very fond of speaking of the advancements made in dentistry, and of calling it an art and a science. Now, it is true that dentistry has developed to a great extent, but we cannot claim that it is really a science unless it meet all the requirements of a science. For one thing, those who write or speak on dental subjects should use scientific terms. If you look you will find that throughout the realm of science, in a great majority of cases, and particularly in the more modern sciences, the words and scientific terms used convey a definite idea. That is scientific; it is exact. We have had a gradual evolution in the matter of nomenclature, and we find that in medical science, as well as in our own profession, we have been gradually eliminating those terms which include the names of persons. We have been striking out here and there the name of the individual, and giving to a part the word that indicates what it is.

We used to speak of Riggs' disease, but now it is "pyorrhea alveolaris," which is not a good term for that disease, although it expresses the idea in a way that all understand. We formerly said antrum of Highmore, but now it is the maxillary sinus, a term that expresses exactly the idea of a sinus situated in the maxillary bones. We want to continue advancing in this direction and must therefore eliminate the terms that do not express an idea accurately, and when we coin new terms they should be distinctly definite. The English language is limited in its capacities and resources, and so we are often obliged to borrow from other languages; while on the other hand, other languages return the compliment. The science of electricity has taken nearly all of its terms from the Greek,

and in dentistry we have borrowed many words from both Latin and Greek.

In the matter of improving our nomenclature we have been doing something, but we are moving very slowly. Dr. G. V. Black presented a very valuable paper on this subject before the Columbian Dental Congress in 1893, and afterward committees were appointed by the National Dental Association, in the years 1895-96, to study the subject. Nomenclature was included in one of the sections of the Fourth International Dental Congress, and now we have the subject included in one of the sections of this organization, so that every year something is presented in connection with it. The Institute of Dental Pedagogics, composed entirely of teachers, has taken up the subject, and last winter at the meeting held in New York, a commission was appointed with authority to appoint subcommittees to select proper men that would carry on the work in a systematic way. If the members of the commission can agree upon a definite system of nomenclature, the schools, journals, and writers will adopt it, and in that way it will be spread throughout the realm of dentistry.

It is very unfortunate that we should have to employ so many words that are inaccurately applied. It has annoyed me for many years that dental dealers should speak of tweezers as pliers. The reason given by them for so doing is that the profession has called them pliers, and so they continue to use the term. We are to blame, to a great extent, because we continue to use these terms that we know are incorrect, for we should adopt the proper words in speaking of instruments and in everything, and I hope that eventually many of these incorrect terms will be eliminated.

In the matter of absorption, Dr. Wilson draws a line of distinction between absorption and resorption, and his definition is correct in at least one particular. He says resorption is the removal of waste products, but the alveolus is not a waste product; it is removed because nature has no further use for it; its space is more desirable than its company.

We have a method of soldering which some call autogenous soldering, while others call it sweating. It is not welding, as Dr. Wilson says, because there is no force used in the process, and he prefers the term sweating. Neither sweating nor autogenous soldering express the idea exactly, but I think the latter term is to be preferred. He also objects to the name cap crown when used instead of shell crown. I think shell crown is to be preferred in that case. In regard to the word karat, we find that he prefers spelling it with c, and quotes many authorities who prefer the c to the k. He also gives it spelled with k as a second choice, but I think we should drop that entirely and use only the c, because so many of the authorities prefer it.

With reference to the word carborundum: I was very much surprised to find that it is not to be found in Gould's dictionary.

Over the terms "cast" and "model" I have struggled for many years. Dr. Grant Molyneux tried to convert me to the views Dr. Wilson holds with regard to the significance of the two terms, but while he did not succeed then, I think Dr. Wilson has converted me now. I believe *cast* should be used in reference to vulcanite work, and *model* when a thing is to be reproduced in metal. It seems a good distinction to make in the use of these terms.

Speaking of the word collar crown, he suggests that term as an improvement upon the Richmond. It has always been a question as to whether Richmond should have the credit for that crown, and I think the preponderance of evidence is that he did not originate it, and I believe collar crown is to be preferred, because it embraces all the features of that crown. Under the head of crowns, he says that there are two kinds, one attached to the root by means of fixed dowels, and the other by means of detached dowels. There is another class of crowns requiring no dowels at all. We often insert them on anterior teeth that are greatly worn down.

I do not think we ought to change the spelling of words arbitrarily, but the

word gauge, in my opinion, should be spelled gage.

In regard to impression cup and tray, we have been in the habit of using the term impression cup, but, as Dr. Wilson says, cup conveys the idea of capacity, while tray implies that which holds and carries; therefore we should use impression tray rather than impression cup.

As to the lingual surface of the teeth, the essayist says that the term palatine should not be used, but prefers lingual, because the inner surfaces of the teeth of both upper and lower dentures are next to the tongue.

We formerly spoke of the superior and inferior teeth, but the terms are not distinctive enough. Superior and inferior refer to quality as much as to position, so we should adopt the terms upper and lower instead. Upper and lower possibly do not sound as elegant, but they are quite proper. The medical profession use superior and inferior, and we copied their words.

I like Dr. Wilson's criticism of the word *prosthodontia*, that was introduced some years ago by one of our dental editors. It was suggested that as *orthodontia* was a good word for the correcting of deformities of the mouth and face, *prosthodontia* would be a good word for prosthetic dentistry, but when we consider the Greek roots from which the word is derived, it will be seen that it is not a correct word. It does not fully express the idea, and while it seems to be in line with *orthodontia*, it does not express as much as do the terms *prosthesis*, or *prosthetic dentistry*.

In regard to another point: When we make a bridge we usually have two abutments or piers, and between these piers we place crowns that we call dummies. That term has come into use because they were so called in the early days for lack of a better word. As yet we have no better word to express that idea, and Dr. Wilson suggests the word *substitute*. That is not good, because it is not sufficiently definite. I do not think that we should abandon the old word until we find one that expresses the idea accu-

ately. The great point in nomenclature is to adopt words having definite and explicit meaning.

Dr. J. H. Crossland, Montgomery, Ala. I wish to add only a few words. I notice that the essayist prefers the use of the word *absorption* as applied to the taking up of nourishment, and *resorption* to the taking up of waste products, etc. There is a good reason for this distinction. If we go still deeper than he has gone into the study of the etymology of these words, we find that the word *absorb* comes from *ab*, away, and *sorbere*, to suck, which in its strict sense means to take up or away. *Resorb* rather means to suck up again, that is, to take back something. The word becomes more forceful and I think the distinction decidedly correct and happily made.

Truly the student of etymology finds that the dead languages do not change, but our knowledge of subjects changes. I have thought of two or three words during the course of the discussion that come under this head. For instance, the word *electron*, which means amber. In olden times the Greeks knew that if they rubbed amber the friction would produce a force which would attract particles of other substances, and the evolution of nomenclature has brought us the term *electricity*, which conveys no suggestion of amber save to the student of etymology.

If we go outside of the technical terms we find the same condition of things. For instance, the word *dilapidated* comes from *di*, apart, and *lapis*, a stone. In its original significance it meant a condition of a structure built of stones in which the stones were falling apart, hence could not properly be applied to any but a stone structure; but now time and custom have changed that, and we may correctly say that a wooden building is in a state of *dilapidation*. I mention these instances simply to show that nomenclature is frequently a compromise. We cannot always find words to express the exact meaning we intend to convey, because in a great many cases we do not understand the subject thoroughly. We may express what a subject

means now, and next year it may mean something else.

I am in favor of classical derivatives in all cases where they can be reasonably retained or introduced. They add to the strength and dignity of language; conduce to order in science; illuminate the path of research, and inspire the student to basic culture. I do not think it well to change a word unless there is a very good reason therefor.

With regard to the derivation of karat, there is another derivation that the essayist might have mentioned. Way back in early Egyptian times karat meant a grain of wheat which was used in weighing precious metals, etc., and they spelled it with a k or a similar letter, and that is the reason we use k instead of c.

With regard to the term pyorrhea alveolaris, just as Dr. Guilford says, it does not express the whole idea, but it probably comes as near to it as any descriptive derivative—if I may use such a term. But sentiment, and only sentiment, would entitle Dr. Riggs' memory to perpetuation in connection with it.

Dr. JAMES McMANUS, Hartford, Conn. In discussing the subject Dr. Guilford speaks of Dr. G. V. Black as one of the first who wrote on this subject. I think we can go farther back still—to the writings of Drs. Atkinson and Corydon Palmer. It has been a matter of surprise to me that my friend Dr. Guilford, in the many years that he has been interested in this subject, has not taken a more active stand in forcing his scientific ideas on the profession through the medium of the association. If he wished to do here what should have been done in the National Association of Dental Faculties, he would insist upon a committee being appointed, consisting of representatives from each college, for the purpose of devising a system of dental nomenclature, to be published in book form under the auspices of the association, and later on adopted by teachers. These little books on nomenclature could be given to each student, who would be guided thereby in his selection of terms. I am glad to hear Dr. Guilford say that there has been some little move made in

this direction, but it is likely that it will be as slow as it has been in the years past, unless we work systematically and earnestly, and the only practical way that I can see is to have these little pamphlets or books published. After they have been in use for one or two years, the publishers of dictionaries will be glad to incorporate their contents in their new editions. If we can secure proper support it will take but a short time to select the proper terms and to place them in the hands of the students.

Dr. GUILFORD. That is what I have done. At the last meeting of the Institute of Dental Pedagogics, which is composed entirely of teachers, there was a paper presented on the subject we have been discussing. The suggestion was made and adopted to select the proper men to go over one or two subjects each year, and to refer their report to a committee to criticize and improve it if possible. The report with correction would then be presented to the association, which after passing on the report finally, would send a list of accepted words to the journals and colleges. The next year two, three, or more subjects would be taken up, and so on, until all the subjects of dentistry would be covered.

The next order of business was the reading of a paper by Dr. J. H. Crossland, Montgomery, Ala., on "Prophylaxis a Factor in Dental Education," as follows:

PROPHYLAXIS A FACTOR IN DENTAL EDUCATION.

Webster's International Dictionary defines prophylaxis as "the art of preserving from or preventing disease," etc.

The exponents of what some see fit to denominate "the new departure," with seemingly perfect unanimity, recognize the necessity of frequency and periodicity in the application of this art to the treatment of the human mouth. In the client who returns with punctilious periodicity for examination and advice, and such services as may be necessary, and who is intelligent and tireless in his efforts to obey instructions, we find one extreme;

at the other is the patient who comes to us only to seek relief from pain. Probably no practice is without these extremes or any of the degrees between them. At the latter extreme, and the degrees between it and the first mentioned, we have a class of *clientèle* whose enlightenment is one of the great problems of the dental education of the period. "Doctor" in its primal significance meant teacher, but it does not now bear that significance. This applies, especially, but not exclusively, to the lay mind.

Daniel Webster believed that inspiration or preparation was absolutely essential to a consummate utterance. Indeed the solution of the aforesaid problem will require both preparation and inspiration—inspiration on the part of the patient, and preparation and inspiration on the part of the practitioner. The heart of the teacher must throb in unison with the import of the words he utters and the lessons he would teach. The most eloquent words the human tongue may speak are useless if the soul of the speaker is not attuned to the spirit of his theme.

Mechanical, surgical, and therapeutic procedures in their varied forms and many aspects have brought degrees of relief from those ills with which civilization and lack of function have afflicted the oral cavity.

Our art has struggled forward, buoyed and led by untiring genius, its meandering course bringing it at times within the rays of that great beacon of human progress—the light of science. And thus has its partial attainment of its destiny as a specialty in the great economy of human effort brought to the zealous and worthy of its votaries that *sine qua non* of all human advancement—inspiration to further progress and higher attainment. Perfect consummation of even our dominant theories and hypotheses of former years could have resulted in only an approach to such conditions as nature designed. But the object of the prophylactic treatment of today is far above and beyond this—the maintenance of natural conditions—and the ideal of today, in the eternal fitness of

things, is higher and grander than any other period of our development has ever known.

A woman's neglected mouth—an accumulation of calculi and débris in wild profusion, teeth opaque and lusterless, gums all bleeding and sore—a foul, filthy, repulsive, and dangerous mouth—an approach to a disease, loathsome, horrible, maybe incurable—prince of oral diseases; cheeks sunken and innocent of color, eyes lusterless, languid, and wan; and through this mouth passes nourishment for this mother and her child!

A few months of the application of prophylactic treatment with unflagging energy, punctilious periodicity, and strict obedience to instructions, and behold the changing picture! Gums are coral now, and the stiffest bristles reddened not upon them more. To the teeth the mingled gleam of ivory and luster of pearl is returning, and translucency in its vital glow and splendor; back to the rounding cheek the rose tint is creeping, and the fire of life and aim again is kindling in the twinkling eye. A troop of young hopefuls are filling appointments with a punctuality which betrays maternal inspiration. Verily, the heart that throbs not with professional pride in the presence of such a picture must be immune alike to the beauties of esthetics and the grandeur and glory of the high and holy spirit of ethics!

The proceedings of our meetings and the pages of our journals teem with theories and hypotheses as to means of enlightening the masses regarding the necessity of dental services and advice; and pages and pages of logic and eloquence have been expended on this topic with seemingly no adequate results.

In the so-called "new departure" which is constructively such, a most splendid opportunity is presented for the dissemination of such enlightenment. Were schoolboys taught one day of every month, and allowed to devote all the other days to play, how much of their curricula would they assimilate? How much of our instruction does the average patient assimilate sufficiently consummately for guidance during the long, per-

haps yearly, intervals between visits to us? How different is this assimilation by those clients who make monthly visits for hygienic care? Read the answer where minute stoppings forestall caries' ravaging blight; where, in prodigal profusion of curved lines, coral gums embrace, in matchless symmetry, graceful forms of dainty ivory, and immaculate surfaces of gleaming pearls charm the vision of those whose souls are congenial with the good, the true, and the beautiful! There is an inexpressible sense of cleanness which delights the refined, and the cultured client enthuses over the lustrous vitality, comprehending the significance of periodic supplementation of function effected in accordance with the mandates of that mysterious force which imparts rhythm to the movements of the universe.

In short, and in conclusion, constant observation of pathological conditions, and systematic and inspired effort to reach the ideal—the physiological—will, in the natural course of things, furnish incentive to deeper and more thorough study and research into these important and basic subjects. The closer relation and better understanding between practitioner and client, which will come to them, will redound to the great good of the latter and to dentistry, as well as to the worthy practitioner. The public is gradually, if slowly, coming to realize that a dentist should be something more than a mere mechanic; that, forsooth, intelligence, culture, and refinement are necessary to his symmetrical professionalism. This has been learned by some even from the irregular contact with him which has so long and so generally prevailed. The frequent and regular intercourse between him and his client is replete with opportunities for the observation of the degrees in which he has attained to these requisites; and its effect as to the enlightenment of the lay mind is destined to become a mighty factor through that beautiful law of compensation which finds expression in the survival of the fittest.

The chairman announced as the next order of business the reading of a paper

by Dr. H. HERBERT JOHNSON, Macon, Ga., "A Review of the Methods Employed for the Retention of Fillings."

[This paper was printed in full at page 362 of the April issue of the DENTAL COSMOS.]

Dr. N. C. LEONARD, Nashville, Tenn., then read a paper entitled, "'Pressure Anesthesia' and the Removal of Living Pulp," as follows:

"PRESSURE ANESTHESIA" AND THE REMOVAL OF LIVING PULPS.

No development in dental science during the past twenty years deserves a more prominent place in the esteem of our profession or a more conspicuous place in its literature than the procedure known as "pulp extirpation under pressure anesthesia," for perhaps no other method introduced during recent years has been of more real value to the intelligent operator, or of more comfort and benefit to his patients.

At the time of its introduction, more than ten years ago, dentistry must have felt the need for a more satisfactory and scientific method of pulp-removal; yet its slow adoption and the half-hearted manner in which it is employed today would still indicate an uncertain or distrustful attitude, wholly inconsistent with progressiveness in modern surgical procedures.

The use of devitalizing agents had for many years proved a more or less satisfactory treatment in cases demanding pulp-removal; and the ease of such applications must have exaggerated the seeming difficulties of the new method, without suggesting its advantages to the operator who is content to follow the course of least resistance, and drift with the tide. But without going very deep into speculation as to reasons for the lukewarm reception to so valuable and scientific a method, I will broadly charge the delay to those faithful adherents who have failed to supply dental literature with suitable testimonials, and will proceed with an endeavor to meet my own delinquency.

With the hope of adding a little more weight to the arguments I shall use in my discussion of the subject, I will begin by stating that for the past ten years I have used this method exclusively in my practice, treating, certainly, more than a thousand cases without, to my knowledge, having had a single case to end in abscess or pericemental infection. A very few cases of partial failure could be readily traced to faulty manipulation, and they only serve to improve my technique and increase my faith. Such a clinical result as this could hardly be accidental, nor could the success be due to the selection of favorable cases, since this report includes all cases which demanded pulp-removal as they presented—with a very few exceptions which I shall mention later—and embraces a very large percentage of cases where the exposures were most difficult of access, and in patients of all ages and variety of temperament.

Theoretically the method seems to approach perfection; clinically its possibilities should only be limited by the intelligence with which it is applied and the dexterity of the operator.

In the light of modern surgery it must be admitted that in a surgical operation where living tissue is involved, the only assurance of ideal results is a clean field of operation and sterile instruments, followed by a non-irritating and antiseptic dressing.

With the aid of pressure anesthesia the removal of the living tooth-pulp becomes a simple surgical procedure, to which all the principles of modern surgery apply; and it must be admitted, again, that an ideal result must be obtained where a live tooth-pulp is aseptically excised at the apical end of the root, and the removal is followed by an antiseptic dressing to the remaining stump, and complete filling of the root-canals.

The only question that admits of argument is whether or not this can be accomplished in a sufficiently large percentage of cases to justify us in adopting it as a routine method of treatment in all cases demanding pulp-removal.

My own clinical experience is to me the best argument; and while I do not

claim, nor believe, that in my practice there has not been a very considerable percentage in which the ideal conditions suggested above have not been accomplished, my uniformly successful results would indicate that we may safely allow ourselves some latitude in deviating from the ideal, provided our technique includes a remedy for the imperfections. Certainly, I would not attempt to claim, nor do I believe it possible to accomplish, the excision of the pulp just at the ideal point—the apex of the root—and its removal perfectly in every case; neither do I believe it possible to have always a sterile field through which to operate; so I prefer to treat the subject from a practical standpoint rather than from that of the idealist.

To recite briefly the technique the results of which I have found so satisfactory, will perhaps enable me to better present my reasons for deviating from what would appear to be the accepted teachings of authorities who have written most plausibly on the subject, and whose teachings I believe to be in some important respects unscientific and misleading.

The term pressure anesthesia as used in this paper is not meant to include the operation of forcing an anesthetic agent through the structure of the dentin by means of a special instrument, but only the simple form used for anesthetizing exposed pulps. The method is very simple, and may be easily and successfully used in any cavity where an exposure may occur, from the third molar forward.

After excavating the cavity slightly by breaking down all frail enamel edges, and removing such loosened material as would interfere with an actual exposure of the pulp, the cavity should be thoroughly washed with warm water. If the location of the cavity permit it, the rubber dam should be adjusted, though if the operator be careful this is not essential to success. After cleansing the cavity as suggested, being sure that an actual exposure exists, I usually apply a pellet of cotton saturated with an agent that is both disinfectant and analgesic, allowing it to remain for two or three minutes. For this purpose I prefer to use carbolic

acid, on account of its sterilizing and anesthetic effects, and also because it prepares the pulp-membrane, by virtue of the escharotic action of the acid, for more ready entrance of the cocain.

By the use of soft yellow wax, pressed into place with slightly moistened pellets of cotton held in a pair of pliers, the most awkwardly shaped cavity can be made into a very simple one for the application of the cocain—barricading, for instance, the interdental space by building in the soft wax, and converting a difficult approximal cavity on the distal surface of a molar into a simple funnel-shaped cavity with the pulp-exposure at the apex of the funnel.

I use powdered cocain moistened with enough adrenalin solution to make it into a paste that can easily be transferred on the point of an instrument to the point of exposure, applying, perhaps, on an average, about one-quarter of a grain of cocain. This pasty mixture becomes more fluid upon contact with the pulp, partly by the exudates from the pulp and partly, perhaps, on account of the warmth of the tooth. By allowing this agent to remain in contact with the pulp for one or two minutes, the membrane of the pulp is generally sufficiently anesthetized by osmotic action to render the remaining part of the anesthetizing operation almost entirely painless.

A pellet of wax is then placed in the cavity in such a way as to confine the fluid cocain against the pulp, and at the same time to exclude as nearly as possible any bubbles of air that might displace the fluid. Then by slight pressure on the wax, either with the finger or a pellet of cotton held in the pliers, the pulp is instantly anesthetized, and may be immediately removed.

After removing the wax from the cavity at the point of exposure, I flood the cavity with a good antiseptic, usually one of the essential oils; then with a sterilized bur held in the engine handpiece I extend the cavity, if necessary, to allow for a ready entrance to the root-canals, in order to bur out the bulbous portion of the pulp. After removing the debris, and again flooding the cavity with an

antiseptic, I proceed with barbed canal broaches—which have been previously sterilized—to remove the pulp from the root-canals. This is usually, except in single-rooted teeth, the most difficult part of the operation, and being of much importance should be done at the expense of time rather than at that of thoroughness. If the anesthesia be not complete, it may be supplemented at any time by additional applications in the same manner as at first.

If the pulp has been removed from one canal, and in others is found to have partially regained its sensitivity, the first canal should be carefully filled, and then the anesthetic agent be reapplied to the others, until each filament, so far as is practicable, has been removed. Broad, flat canals, or those that are very small or much constricted at the entrance, together with anomalously shaped teeth, often constitute complications that tax our ingenuity and modify our success.

But these are difficulties that must be met with in any method for the removal of the pulp. In the light of my own experience and observation, it is obvious to me that if some of the contents of the canals cannot be removed, it is much safer to render such fragments of pulp tissues sterile at the proper time rather than to have to treat a septic condition later on. Many of the difficulties of extirpation are minimized by experience, but it is safe to say that no operator, however skilful, can in every case remove all the pulp tissue.

However, thorough and complete extirpation is not in itself a guarantee of successful results. As in other surgical operations, the most important factor is asepsis, and at every step, from beginning to end, aseptic precautions should be observed in pulp-removal.

While I advocate all reasonable aseptic precautions during the operation, I am much inclined to allow my clinical experience to lead me to the belief that the danger of pericemental infection from this operation has been somewhat exaggerated by some writers.

When we speak of an aseptic operation the term is used only relatively, since we

know that no surgical operation is absolutely aseptically performed. It is even admitted by the most eminent surgical authorities that no operation is ever free from pyogenic and other inflammatory infections. We know, however, that normal tissue will tolerate a certain amount of infection, and while this fact should not influence us in our efforts to secure asepsis, it will help us in a measure to account for our good results!

The presence of an ulcer on the surface of the pulp should not be a reason for the postponement of the operation of extirpation under pressure anesthesia. The facility with which we are able to apply readily such strong disinfecting agents as carbolic acid, creasote, etc., will enable us to so nearly sterilize the septic area as to make the progress of the operation practically safe.

The surgeon who removes a septic appendix, ligating the base and cauterizing the stump with carbolic acid, gets as good results as the one who carefully everts the stump in order to throw all the originally infected area outside the peritoneal cavity. Certainly the peritoneum is more sensitive to infection than the tissue with which we have to deal.

Admitting that a very small amount of septic matter remains on the surface of the pulp, this would not seem to me to be a serious menace to the pericemental tissues, when we consider that it would have to filter through the entire length of the pulp, and that the tissues liable to infection from this source are to be immediately removed under surgical precautions that would inhibit the further distribution of these toxic agents.

When the pulp has been removed my invariable rule is immediate filling of the canals, and this I consider the greatest safeguard against pericemental infection. If all reasonable aseptic precautions have been observed in removing the pulp, I cannot believe that there could be a more favorable time for filling the canals than immediately after the extirpation, while we have the greatest possible assurance that they are sterile. To delay this part of the operation for a subsequent sitting would be but to double or treble the

chances of infection, without offering any compensating advantage, and would deprive us of the use of the best means at our disposal to combat and render innocuous any septic or infectious material that may have been introduced into the canals during the operation.

Certainly no progressive surgeon, after performing an aseptic operation for appendicitis, could be excused for leaving the wound open for subsequent examination to see if everything is all right. He removes the appendix, ligates the stump, manipulates the tissues as little as possible, and closes the wound permanently with an aseptic dressing, which he does not expect to remove until the wound has healed.

The proper filling of the root-canals after the extirpation of the pulp is simply the application of a suitable and permanent surgical dressing for the protection of the living tissue at the end of the root, and is efficient in proportion as the filling is aseptic, antiseptic, non-irritating, and stable.

As a result of extirpation of the pulp there is often considerable and persistent hemorrhage, and the presence of this condition is urged by our authorities as a positive indication against immediate root-filling. To me, their reasoning appears illogical and their position indefensible. The very best device possible for controlling hemorrhage is mechanical means, and I can see no reasonable objection to the immediate introduction of a permanent root-filling for this purpose. Assuming that the operation so far has been done with due regard to cleanliness and asepsis, there should be nothing to fear if we stop the flow of blood with an antiseptic and non-irritating dressing placed in contact with the bleeding stump.

The blood itself is sterile, and if we observe the same precautions in the preparation and introduction of the filling materials as were observed during the extirpation of the organ, there could certainly be no more reason to fear infection than if the hemorrhage had not occurred. If there be danger from a clot in the apical region, then there would be less dan-

ger with the root filled, for the reason that there would be less space for a clot, and the chief avenue of infection would be shut off by the filling.

I cannot conceive of a surgical operation of any kind being completed without leaving a certain amount of free blood to coagulate in the wound; but in the case just mentioned the amount of free blood left would be inconsiderable and insignificant as compared with that left by the most careful operator in an abdominal section, where the wound is immediately closed and permanently sealed with the assurance—in non-septic cases—that if no infectious material has been introduced by the operator, the small clots will not affect his results.

If persistent hemorrhage through the canal after extirpation should deter the operator from performing the immediate-filling operation, the clot that would surely be present at a subsequent sitting would be a much more serious menace to a successful result, in my opinion, than the presence of a coagulum in the first instance. With the root-canals properly filled, the chances of a secondary hemorrhage, against which we have been repeatedly warned, do not seem to me to deserve serious consideration.

As a root-filling material for this class of cases, that which I have adopted—and which seems to meet the requirements—is a paste made by mixing two parts of a coarse cement powder and one part of aristol with oil of cinnamon or any other essential oil or antiseptic agent. This can be introduced with smooth broaches into the bleeding canal, thus partially filling it. Then, with pellets of cotton held in the pliers, the paste may be forced into the canal as the blood is forced out, and packed as hard as may be desired. The cotton pellets, besides forcing the paste into the canals, absorb the blood and excess of fluid from the paste.

If there be any reason to believe that any considerable quantity of free blood has been confined in the apical region beyond the paste, it may be allowed to escape by passing a small, smooth broach through the paste to the end of the canal,

subsequently closing the opening with a sterilized gutta-percha canal-point. I use this paste as a permanent dressing in all canals where I have practiced extirpation, generally supplementing it with a gutta-percha point, and packing the paste with cotton pellets, using always considerable force to make it as dense as possible, and at the same time to force it into all irregularities of the canal.

I do not urge this as the only or the best method of filling root-canals in this class of cases. As it has proved itself satisfactory in my hands, and as it seems to be non-irritating, permanently antiseptic, and is easily adapted to all cases, it may appeal to others.

Among the cases I have treated by this method there have been many in which I was unable to remove all pulp tissue from every canal. From many canals in the buccal roots of upper molars and the mesial root of lower ones, too small to admit of entrance with any ordinary nerve-broach or so constricted as to admit the broach to only one-third or one-half their length, I have found it impossible to remove all the contents. In these cases, if I cannot remove the pulp, I always leave it in. This is at least the philosophic thing to do, and I do not worry over any possible failure. I do not in such cases hesitate to introduce immediately a permanent filling.

After filling the other canals in the usual way, I flood the whole cavity with the antiseptic that was used in making the paste for the root-dressing, working it with the smallest nerve broach as far in beyond the remaining stump as possible, then applying the paste directly against the bleeding stump, and with pellets of cotton held in the pliers, packing the paste firmly, using a considerable amount of force, in the hope, at least, of injecting the canal or the pulp-filament with the antiseptic.

This will no doubt be criticized as being unscientific. Perhaps it is. I should like, myself, to have a method more in accord with accepted scientific theory. I shall not attempt to defend it as scientific, but will report only my results. So far as I know, I have never had

a case of this kind to end in abscess formation. A small percentage have manifested slight temporary soreness, but the percentage has not been larger than in cases where I had reason to believe all the pulp tissue had been removed. A striking fact is that none have shown neuralgic symptoms. In the majority of cases where slight tenderness or soreness has been present, I have generally attributed this symptom to traumatism, sometimes to mechanical irritation of the root-filling, or to incorporated air. But very few of the cases have had recurrence of this symptom.

My success with the method I have attempted to discuss I do not attribute to any unusual degree of skill on my part, but to the correctness of the principles on which the method is founded—true surgical principles.

The knowledge that many of my operations have been very imperfectly done without seriously affecting the results has added largely to my faith that it is the true method, and that it will ultimately prevail against the use of devitalizing agents. As stated before, I have found it applicable to nearly all cases requiring the removal of living pulps. The cases of which I have made exceptions would not amount to more than two per cent., and include but two or three cases in which the pulp tissue seemed to possess an idiosyncrasy against cocain anesthesia, and even in these I have suspected some faulty manipulation in applying the anesthetic.

In another small percentage of negative results I have found the cause to have been a partially devitalized condition of the pulp, the dead portion barricading the way by its valve-like action, and preventing the ingress of the anesthetic.

These, with a few cases of timid patients, constitute all those in which I have been unable to utilize the method under discussion.

Pulp-stones have often been difficult complications, but I do not now remember a case of this kind in which I have been forced to resort to a devitalizing agent.

Discussion.

Dr. W. H. LEAK, Watertown, N. Y. The paper we have just heard shows the care the essayist has used in its preparation, and the thoroughness with which he performs the operations he has described, a factor which in a great measure accounts for the success he has had in such a large number of cases. He alludes to the very small percentage of cases in which he has not been able to obtain anesthesia by the pressure method, owing to the presence of a slightly disorganized pulp, and I note that in such cases he uses carbolic acid prior to the application of cocain. I am unable to understand why he uses carbolic acid, which we know is a strong coagulant that would render the pulp more difficult to anesthetize.

With regard to the thought that he brought out in connection with the filling of the root-canals after extirpation of the pulp: I have wondered if I misunderstood him in thinking that he said that he filled the canals even in the presence of a slight blood exudate, and that no trouble ensued, either in the form of an abscess or of pericemental infection. It seems to me that it would be best to wait until the flow of blood has ceased before filling the canals.

I had one peculiar case in connection with the extirpation of pulps with cocain that I would like to relate, and to ask whether any others have had a similar experience. It was the case of a strong, healthy woman, about forty years of age, in whom I used a solution of cocain and adrenalin. After pressure on the pulp had been exerted for a minute or a minute and a half, the patient raised her hand in an endeavor to stop the operation, and I removed the rubber dam after inserting a small pellet of cotton into the cavity. The patient then told me that she was feeling very faint, and complained of an oppressive burning sensation that lasted for a few minutes, after which she recovered completely.

Dr. J. H. CROSSLAND, Montgomery, Ala. I am not opposing any of the views expressed by the essayist, but if there is

anything which has been impressed upon me by considerable clinical experience, it is that there should be a period of rest and drainage after the extirpation of the pulp, before the canals are filled. If they be filled immediately after extirpation there is a greatly increased danger of discoloration of the tooth. We may easily talk of the scientific methods of removing the contents of the tubuli, but when we fill these teeth immediately a large percentage of them will discolor and break down, and the red blood corpuscle will get in its work.

In regard to the application of cocain in powder form: After the pulp is exposed and the cavity dried, a piece of the pellet is placed in contact with the pulp, and when the cocain has become moist by the exudation from the tissues, pressure is applied, and anesthesia usually results.

I did not understand the essayist's remarks with regard to mummification. I thought that it was a thing of the past; that progressive dentists did not attempt to mummify a pulp, except in cases where it was found impossible to remove it entirely.

Dr. CHARLES McMANUS. I would like to offer a suggestion as to the first two words in the title of the paper, and that is the expression "pressure anesthesia." We have just had a paper on nomenclature, and it occurs to me that pressure anesthesia is not a good name for that procedure, although it is the term in general use. I do not know that I can present a better one, but it seems to me that there should be some exact term applied to the very important operation of cocain pressure anesthesia.

I have enjoyed hearing this very instructive paper by Dr. Leonard, and am particularly pleased with the way in which he has presented the subject. The results he has obtained are most satisfactory and encouraging, and the essay itself is a model, as a short, clean-cut, scientific paper.

Dr. W. D. MONROE, Washington, D. C. I think if the essayist will use adrenalin in connection with the cocain, it will do away with the hemorrhage in nearly every case. The cocain and adrenalin

can be obtained in tablet form from any druggist, and is very convenient to use.

Dr. LEONARD (closing the discussion). I would like to thank those who have taken part in the discussion for the interest manifested in the subject, and for the compliments paid my paper. I trust that I have shown what I endeavored to show—a scientific spirit in the investigation of this subject. I tried not to be dogmatic in any of the statements made, and I certainly hold myself ready to receive any suggestion that may be an improvement on the technique that I have suggested, or in the treatment of these cases.

I will just refer to some of the points mentioned by those who have discussed the subject. Dr. Leak spoke of the use of carbolic acid previous to the application of the cocain. My reason for it is threefold: In the first place, carbolic acid being a powerful sterilizing agent will, to a degree, destroy any septic matter that may be present at the exposure. Sometimes there is a little pus present, and by such means I endeavor to destroy any material that may be the cause of it. I also use it on account of its analgesic and anesthetic effects, as I think that the carbolic acid renders more favorable the entrance of the cocain into the tissues, and while I do not wish to make a positive statement about this point, yet I feel that in many cases the anesthesia is produced more quickly where the carbolic acid is used than where it is not, and that perhaps the coagulum formed on the pulp tissue is more favorable to the osmotic action that carries the cocain into the pulp.

The case reported by Dr. Leak I consider a coincidence; the same symptoms would probably have been noticed had no toxic agent been used at all. I frequently have had cases in which although no agent whatever had been employed, symptoms occurred that I would probably have attributed to cocain if I had used it. I have very seldom seen any constitutional effects following the use of cocain by the method I have described. I can recall but one case where I was sure at the time the cocain had caused the toxic effects, and I suspected then that

some of the fluid had leaked through, and been swallowed by the patient.

As to drainage I can say that it is not necessary, if we have been careful in our antiseptic measures during the removal of the pulp. If we have been careful we will have as nearly as possible a sterile field. Why not apply a surgical dressing, just as the surgeon does in the case of major operations? After he operates he places a dressing to protect the tissues that have been wounded, and leaves it in place expecting that it will keep the tissues aseptic until the wound has entirely healed. It is simply a surgical procedure, and I think we are thoroughly warranted in using the same methods in dental surgery, where we have reason to believe that the operations have been done aseptically, as are used in surgical major operations. As far as drainage is concerned we get better results without drainage, by lessening the chances of infection, as surgeons do in abdominal operations performed under aseptic precautions.

As to mummifying: I did not use the term mummifying at all, because I did not want to be regarded as an advocate of mummifying pastes, etc. The only reference I have made to this paste is where I have used it as a dressing simply, in cases where I could not remove the pulp tissue, where the canals were too small or tortuous, or where there was some physical reason why the pulp tissue could not be removed. In no cases do I

leave the pulp tissue in the root-canals, except when it is absolutely impossible to remove it. But in those cases where I have used this paste as a dressing to remaining stumps that I have been unable to remove, my results have been satisfactory, for at least I have never had to contend with abscesses, or other serious after-results.

I agree with Dr. McManus that pressure anesthesia is not a suitable term to designate these operations. I used the term in quotation marks, simply to indicate that this was the operation known as pressure anesthesia, and I said that the term as used in the paper was not meant to include the procedure in which special instruments were required to force the agent into the structure of the tooth.

As to the use of adrenalin, perhaps Dr. Monroe did not notice that I said in my paper that I used adrenalin in connection with cocain. I do not know that it offers any special advantage, unless it be that the anesthesia is thereby more easily induced. I began the use of adrenalin in hope that it would inhibit hemorrhage, but so far it has been my experience that it does not lessen it very materially.

Dr. J. P. CORLEY, Greensboro, Ala. I would suggest as a more nearly proper designation for the description of the operation described by Dr. Leonard, the term "pressure cocainization."

There being no further business before Section II, motion was made and carried to adjourn *sine die*.

The Clinics.

Dr. J. A. GORMAN, Asheville, N. C. "Orthodontia."

Dr. Gorman exhibited a large number of casts showing malocclusion of the teeth, and the conditions after treatment.

The clinician laid special stress on—

- (1) The importance of studying first of all the occlusion of the molar teeth.
- (2) The importance of beginning the treatment as soon as possible after the

eruption of the first molars, and of getting these teeth in their proper positions. (3) The simplicity of the appliances used. Only Angle's "D" bands and expansion arch and the Baker anchorage were used for correcting the malocclusion.

Dr. I. N. CARR, Durham, N. C. "Combination Filling of Tin and Gold."

Dr. Carr demonstrated the properties of Ambler's cohesive tin, filling a large compound cavity in a lower molar by building the filling with successive layers of tin and gold. He then removed the filling and cut into it to show the cohesive property of the tin. He also filled a large approximal cavity with Ivory's "crystallia," a shredded tin, restoring the contour by building with the tin on cohesive gold. A cross section of the filling showed that the union was perfect.

Dr. W. H. CUDWORTH, Milwaukee, Wis. "Porcelain Inlay Restoration of a Central Incisor."

In making this restoration the clinician used Jenkins' porcelain, a platinum matrix, and an electric furnace. He obtained good contour, sharp corners, and fine color. Ames' special inlay cement was used for setting the inlay.

Dr. J. A. HALL, Collinsville, Ala. "A Temporary Lower Denture."

With a gutta-percha base and a cement body a temporary lower set can be easily constructed, and the denture worn immediately after the extraction of the teeth. It will protect the wounded tissues and aid in mastication. It will also sustain the lips in a normal position—thus retaining the original facial contour—and will aid in enunciation. Gutta-percha can be extended lower down on the ridge than any metallic or rigid plate, without lacerating the tissues with which it may come in contact. Gutta-percha is not, strictly speaking, an irritant, and is decidedly more cleanly than rubber. It also clings to the ridge with greater tenacity than a rigid plate, and the muscles and soft tissues will tolerate its presence without becoming inflamed.

In cases where necrosis or other causes have destroyed a large area of bone, leaving flexible tissue interwoven with muscular fibers which almost float in any direction, a base of gutta-percha is most certainly indicated.

Dr. E. P. DAMERON, St. Louis, Mo. "The Use of Interchangeable Facings."

The clinician showed an upper anterior bridge of six teeth made with in-

terchangeable facings. The abutments were Richmond crowns, reinforced by having the band of the crown extend down over the gingival margin of the facing, concealing the joint and increasing its strength. He also showed a porcelain-face bicuspid shell crown, using interchangeable facings. The shell crown is first constructed, the buccal surface cut away, and the backing of the facing soldered to the shell. The facing is then cemented to place. The same arrangement for the band at the gingival margin is followed as in constructing the Richmond crown described above.

Dr. C. H. FRINK, Fernadina, Fla. "Porcelain Restoration of Malformed and Diminutive Laterals."

The tooth is prepared with a shoulder at the lingual aspect of the gum margin, sloping the surface at the labial aspect of the gum margin. A shell matrix is formed of platinum, after which a plain vulcanite tooth is approximately ground to fit by cutting out the pins and otherwise concaving the posterior surface. This porcelain shell is held in position with a small lump of hard wax, just warm enough to hold the matrix to the tooth-shell while removing it from the mouth. The matrix and tooth being held in a pair of locking tweezers, the wax is carefully removed, and the high-fusing body applied. After the baking is completed, the matrix is removed, and the inner surface etched with hydrofluoric acid and cemented in position.

This clinic was illustrated with a large plaster cast of an upper left lateral incisor of diminutive size.

Dr. F. E. ROACH, Chicago, Ill. "Moldable Porcelain, Showing its Uses and Manipulation."

The principal field of application for this material is as a substitute for amalgam, in large restorations of molars and bicuspid, and especially in cases where, until the present time, gold crowns have been almost universally used; and also for perfecting the fit of the manufactured porcelain crown. The principal features are that it can be mixed to a putty consistence and molded to any de-

sired form, carved and baked without the use of a matrix. Its advantages are simplicity of manipulation, great strength, and an affinity for the cement when set.

Dr. H. T. STEWART, Memphis, Tenn.
"Bridge Work in Pyorrhea."

Dr. Stewart demonstrated a system of crowning which he has devised for adapting bridge work to teeth badly affected by Riggs' disease. Each crown is made in two separate pieces, the pins and cap being made as for the Richmond crown, after the tooth is cut off even with the gum. This is applicable to the root of any tooth, either posterior or anterior. A second floor is now soldered on the first. The caps are now placed in position on the cast, the facing ground to place—facings can usually be used, even on molars—and backed. Behind this facing is built up in wax a spur which is wrapped about with 1/1000 platinum, and reproduced in 20-k. solder. Over this is then burnished or swaged a pure gold cap to an absolute fit. This and the facing are placed in position, the cap waxed to the facing, removed, invested, and soldered. The cap and pin are cemented on each root separately. The crowns are then placed in position, an impression is taken, and the bridge made entirely separate from the caps and pins. This bridge can be used either as a removable or fixed bridge. Among the advantages are—(1) Being able to shape the root and more accurately fit the bands. (2) The abutments are easily made parallel. (3) Each root can be dried and the cap cemented on separately without regard to keeping the other one dry. This is especially advantageous in first, second, and third molars.

The clinician claims to succeed in making and adapting abutments to teeth affected with Riggs' disease that it would be impossible to save by the ordinary systems of bridge work. The only objection to this beautiful and extremely hygienic system of bridge work is the great tediousness of its technique, which requires much time and skill.

Dr. J. H. CROSSLAND, Montgomery, Ala. "Stomatic Prophylaxis."

This clinic was a demonstration of the method of Dr. D. D. Smith. The lower anterior teeth of a young lady were freed from a very extensive accumulation of calculi, and cleansed and polished until their surfaces were immaculate and smooth. The clinician used a scaler of his own design, one of Dr. Thorpe's, and others of different designs, all, except those used for breaking the thick deposits, being extremely small instruments. The cleansing and polishing were done entirely by hand, the Smith porte-polisher being used. Shoe-pegs, suggested by Dr. H. B. Harrell of Texas, and the usual orange-wood were used as vehicles for the pumice, as well as the following accessories, which have been suggested by the clinician: Small brush made for engine porte-polisher, with bristles cut short; "points" of cow's horn, gutta-percha, celluloid, whalebone, white hickory, black gum, Florida ironwood, and "vulcarbo," the latter incased in rubber tubing and held in the porte-polisher or set in celluloid handles. When roughness or very tenacious stains necessitated a more effective abrasive, the vulcarbo points were used before the application of the pumice.

Very long and extremely thin and smooth orange-wood and hickory applicators were used in applying lactic acid. These, he claims, are very valuable also as detectors of calculi, a certain "grating, tearing" sensation being observed when they come in contact with them, owing to their softness and fibrous nature. Lactic acid, mixed with "balsamo del deserto" to stiffen it and cause it to remain longer in the pockets, was used. He has found that gum-arabic is also valuable as a stiffener for this agent. He advocates periodic—generally monthly—cleansing and massaging by hand, believing that stimulation is as potent a factor as is the cleansing, as shown by the splendid results obtained by Dr. D. D. Smith, of whose method of prophylaxis he is an ardent follower. The instruction in prophylaxis which we give our patients, with the inspiration often de-

veloped by it, is deemed by the clinician of more value than any service that may be rendered by the dentistry of the present period.

Dr. A. W. DOUBLEDAY, Boston, Mass. "Combination Inclined Plane and Retaining Appliance." [This clinic has already been published, as given before the Massachusetts Dental Society: see *Cosmos* for February, page 159.]

Dr. H. B. TILESTON, Louisville, Ky. "Hollow Gold Inlays."

The clinic given by Dr. Tileston on the hollow gold inlay as applicable to molars and bicuspid consisted in the adaptation in the usual manner of a piece of pure gold, 36 gage or even thinner, to the cavity, carrying it thoroughly into the occlusal step, and allowing the edge to overlap the cavity at all points. The step portion is reinforced by packing with crystal gold while in the cavity, and melting into this a bit of 22-k. gold. An outer piece of equal thickness of pure gold is cut to fit just within the gingival margin overlap—the overlap is about one mm. wide—and is tacked at that point with a tiny bit of 22-k. gold. The piece is then replaced in the cavity, the matrix re-burnished, and a pledget or several pledgets of wet cotton are packed between the two pieces to force the outer piece to proper contact with the approximating tooth. The outer piece is then bent over upon the occlusal surface, and the patient is instructed to close tightly upon it, which adapts the thin gold to the occlusion. It is then removed, the outer piece trimmed so that its margin lies within the overlap of the matrix, the cotton removed, and the piece replaced in the cavity for correction. The margins are then soldered all around with 22-k. gold or 22-k. solder. A hole is cut in the matrix piece opposite to the axial wall, through which small pieces of 20-k. solder are dropped and melted in the flame of the Bunsen burner until the space between the walls of the inlay are nearly but not quite full, it being left partly hollow for the cement to enter when set. The approximal face of the inlay should

be finished and polished before setting the inlay, the balance being finished afterward like a gold filling.

The advantages claimed are ease and quickness of construction, as neither an impression nor an investment is required; complete protection of the cement, the overlap covering the joint completely; and the freedom from thermal shock to the pulp of a vital tooth, because of the cement in the hollow space in near apposition to the pulp.

Dr. W. R. CLACK, Clear Lake, Iowa. "Gold Filling."

The cavity was in a mesio-occlusal surface of the upper left second bicuspid. An amalgam filling had been placed in the mesial surface. This had failed in its purpose for want of proper extension and retention. After removing it, the cavity was prepared as nearly after the G. V. Black system as was possible, although the progress of the decay had rendered impossible the squaring of the labio-axial angle. Three half-sheet cylinders of No. 4 annealed soft gold were placed in the gingival third of the cavity, and the filling was completed with annealed gold. The gold was then condensed with a No. 3 Wedelstaedt plugger, the stepping of the plugger having been from the center to the cavity margin. The plugger was held at an angle of ten degrees to the walls and cavo-surface angles. A hand mallet of three and one-half ounces weight was used. Interproximal space was gained by wedging the gold against the distal surface of the second bicuspid, and will be preserved by a contact point touching the same surface. Four and one-quarter sheets of No. 4 foil were used. The rubber dam was adjusted from the upper right central incisor to the first molar of the same side inclusive. A clamp was placed on the molar, but no ligatures of any kind were used.

Dr. V. H. JACKSON, New York, N. Y. "Orthodontia—Jackson System." [This clinic has already been published, as given before the Pennsylvania State Dental Society: see *Cosmos* for February, page 198.]

Dr. J. V. CONZETT, Dubuque, Iowa.
"Gold Filling."

This clinic consisted of the insertion of a gold filling in the mesio-occlusal surface of an upper right first molar. The cavity margins were extended gingivally, buccally, and lingually into the areas of comparative immunity. The cavity itself was prepared with flat gingival and occlusal seats and parallel walls, making no undercuts or grooves, but relying for retention upon the general shape of the cavity and condensation of the filling material. After the cavity was prepared it was varnished with sandarac in order to insulate the pulp against thermal shock, and then the cavo-surface angle was carefully beveled all around the cavity. In filling the cavity non-cohesive gold foil was used in the gingival third, two quarter-sheet cylinders were placed in the bucco-gingival and linguo-gingival angles, and three half-sheet cylinders were forced in between them and the whole thoroughly malleted to place. After this the cohesive foil was started in the bucco-occluso-pulpal angle, and the gold was built forward and over the non-cohesive gold in the gingival third, effectually locking it to place. The hand mallet was used with a ten-pound blow, augmented by a hand pressure which varied from five to fifteen pounds according to the situation of the plugger in the cavity, the light pressure being used when great stress was not indicated, and the heavy upon the occluding surface. No previous separation having been obtained, and there being practically no interproximal space, it was necessary to obtain one, which was done by malleting the gold into the space against the approximating tooth, with the result that ample space was obtained.

In finishing the filling the non-cohesive gold was first sawed out of the interproximal space with a Black saw, and the filling was shaped with Wedelstaedt trimmers and a Black knife No. 7. After this the occlusal surface was ground to form with gem-stones, and the whole filling was polished with sand-paper disks, strips, and pumice on a rubber disk.

Dr. A. P. JOHNSTONE, Anderson, S. C. "A New Method of Fitting Crowns and Making Inlays. Mounting Porcelain Crowns with Fixed or Detached Posts."

The crown was ground to fit the root a little under the gum line on the labial surface of the root, allowed to rest on the lingual surface, and it was ground away freely so that it would not touch the approximal surfaces. The prepared crown was used for taking the impression of the root with paraffin and wax. After the wax had hardened, the crown was removed and invested in two cups attached to the instrument especially devised by the clinician for doing this kind of work. A small button of low-fusing porcelain was made and slipped over the post of the crown, resting between the base of the crown and impression of the root. The instrument was then held in a good hot flame until the button became soft and plastic, when the cups of the instrument were gradually closed, thus molding the button to fit the face of the root. The operation produced a nicely fitting crown in a very simple and satisfactory manner.

Dr. D. H. YOUNG, Attica, N. Y. "The Carbon System of Constructing a Porcelain-face Crown."

In presenting this crown I wish to call attention mainly to the points in which it differs from others, especially from the Richmond crown, because when completed it at first sight resembles more closely that particular crown than any other. These differences consist in the method of making the crown, as well as in the qualities which it possesses.

For convenience we will describe an upper central incisor crown:

Position of the Pin. Since the pin of the crown is its main anchorage and support, to this phase of the work should be given the proper amount of care. Pins of crowns are as a rule placed in about the center of the root, but in this crown that portion of the pin which protrudes from the root is placed at about one-thirty-second of an inch nearer the lingual than the labial side of the root.

This change gives two desired qualities: It affords more room and freedom for placing the facing just where it should be, or use of a thicker facing if desired.

The strength and stability of any structure depend upon its foundation, and in the arrangement of the pin just described I believe we will obtain just these very desirable qualities. During mastication, force is exerted upon the lingual surface of the upper front teeth, upward and toward the labial side, and therefore it will be readily seen that the pin in such a position lengthens the load-arm of the lever, for the tooth and its anchorage being analogous to a form of lever, this arrangement makes it difficult for the crown to become displaced.

Removable Facing. The next point of difference is in completing the crown without subjecting the facing to the flame during soldering. In order to effect this, an impression is taken with the cap and pin in the desired position. The facing is ground to fit the space, and the back surface is beveled on the cutting edge at quite an acute angle. This will leave more space for the solder, and consequently greater strength will be gained. The backing material is now placed upon the facing and swaged or burnished to fit the latter perfectly, the backing being allowed to remain flush at the cutting-edge so as to give the surplus needed in finishing the piece. The backing is then carefully removed so as not to distort it, the surface that comes in contact with the facing is painted with whiting, and sufficient solder is placed upon the cutting-edge and flowed to raise it to the degree of fulness made necessary by the condition of the bite. After this the backing is placed upon the facing, and both are put in the desired position upon the cast; a little wax is flowed from the edges of the backing to the adjoining teeth, care being taken not to get any wax on the pins. It will thus be held in position.

The facing is now removed, a little more whiting is flowed over the pinholes to keep the wax from coming through, and as much wax is added to the other side as solder will be required in the finished crown—but the wax should not cover the cutting-edge, which already has

sufficient solder. By the aid of a small drill the wax is bored out of the pinholes. In order to prevent the solder from filling up the pinholes, small carbons—which can be made from a hard lead pencil—are placed in the pinholes from the labial surface, allowing them to extend into the wax from one-thirty-second to one-sixteenth of an inch, but not so far as to prevent the solder from flowing on their ends and producing the complete contour. A second coat of whiting is usually added at this point, covering the carbons and sealing the joints around them, thus preventing any solder from coming through.

Now the case is ready to be invested, which may be done in the ordinary way. By slightly heating the wax it can be removed without disturbing the position of the backing. As no porcelain facing is present, the case may be heated up as rapidly as desired, and when the solder has flowed, without waiting for it to cool, it may be dipped in cold water and separated in a short time. With the aid of a spear-pointed drill, the carbons and the solder which cover their ends are drilled out.

With a fissure bur held at an angle of forty-five degrees, each hole is cut toward its neighbor, in order that the pins may be bent toward each other. A slight film of cement, light or dark as may seem advisable to influence the shade of the facing, is placed on the occluding surface, and the facing is pressed into place. The pins are then bent toward each other into the slots made for them, and the excess is cut off. Bore out the opening left at the outer side of each pin by placing a drill in them at the same angle at which the pin is bent, and drill to the distance of one-thirty-second of an inch or less, as the case may indicate. Then, with a small retention bur, make this little cavity retentive by slightly notching the pin on one side and the gold on the other; fill this cavity with a pledget of gold or amalgam, and the result will be a facing that when cemented will be clenched and keyed. Finish it, and one is positive that he has a crown with a perfect facing, and with better joints, I believe, than it is possible to obtain by

subjecting the facing to the flame. In addition, the color of the facing will not be changed, as may happen if subjected to the flame.

This crown is a sanitary one, for if in any way there should be a space between the facing and the backing which might absorb food debris, such a space will be filled by the cement. The cement also forms a perfect bed for the facing to rest upon, even at all points, and thus any possible strain through expansion and contraction is avoided—strain which by the ordinary method is often within a few pounds of the breaking-point.

In making a crown by this method the gold is not exposed to view if the contour of the gum is normal.

This method of attaching the facing I have successfully adopted in the construction of bridges.

Dr. CRITTENDEN VAN WYCK, San Francisco, Cal. "The Van Wyck Obtunder."

A disto-mesio-approximal cavity in an upper left central incisor was prepared for a gold filling painlessly by the use of this obtunder.

The result was secured by producing anesthesia in the tooth to be operated upon. A spray of perfumed ether is the liquid used. The device consists of three parts: (1) A combination dam-spreader with detachable nose-shield; (2) metallic tubes for delivering the spray, and (3) a glass receptacle for the liquid. After adjusting the rubber dam a piece of cotton is placed upon the tooth, and the spray is directed on the cotton, which is removed in about three minutes' time. The spray, now directed on the tooth itself, is allowed to continue during the entire cavity preparation.

Twenty pounds of air-pressure will produce the spray, and the evaporation of the ether will render the tooth so cold that three great advantages are secured: (1) Painless cavity preparation; (2) painless grinding for crowns, and (3) painless exposures. There will be no after-effects of any kind. Such a tiny spray is used that there is no possible chance for anyone to be affected by the ether, and the Van Wyck obtunder can

be safely used on any person for any cavity or tooth needing attention.

Dr. F. G. CROUCH, Atlanta, Ga. "Orthodontia."

The clinician showed a number of casts of cases at the beginning of the treatment, after it had been in progress for some time, and at the conclusion of the treatment. Success was attributed to the use of appliances suitable to each case, no one system being adapted to all cases. Special cases need special treatment, and some cases were shown wherein correction could be accomplished by the simplest means—as, for instance, in bringing inward and downward a projecting canine, when expansion is not needed; adjusting a round spring-wire over the canine backward against the first bicuspid and forward against the lateral wall. This when sprung into place gives three movements, and as the tooth comes into position the spring is opened from time to time—say twice a week—which the patient himself may do if properly instructed by the dentist.

A special case was shown of prognathism, due to mouth-breathing and thumb-sucking. Correction was accomplished in one year by using Angle's head appliance and retraction bar, and also by wiring the first bicuspid. A special congenital case was shown of retrusion. The models of the case during the treatment showed marked improvement after a few weeks. The maxillæ were very contracted, and the expansion brought about by the treatment was most marked antero-posteriorly.

Another case showed the Jackson appliance for causing expansion and bringing the lateral incisors into position. After several years on this line of practice, the clinician finds it more and more unnecessary to extract teeth for the correction of irregularities.

Dr. L. A. SMITH, Port Gibson, Miss.

Dr. Gibson demonstrated a method of measurements for ordering facings, crowns, etc., for special cases, whereby the dentist may secure the required shape and color in ordering from the dental depots.

EDITORIAL DEPARTMENT.

EDUCATION AND MEMORIZING.

SOME years ago the editor of *McClure's Magazine* propounded the interesting, not to say important, inquiry—"Does a College Education Educate?" This led to the publication of a symposium of brilliantly written articles by prominent educational authorities all attempting a solution of the riddle. The essential point of inquiry in all of the articles composing the symposium referred to was the one suggested by the editorial query itself, viz, the implied doubt that the college curriculum is educative in the best and fullest sense.

That our educational systems are not all that can be desired, that they do not produce the results which in certain directions we have *a priori* the right to expect, is not by any means a novel thought, and the justification for a belief that they can be materially improved is found in the critical attitude which so many who are qualified to speak with authority on the subject maintain toward it. In the study of this critical attitude it soon

becomes evident that the bulk of criticism is launched not so much at technical knowledge and the schemes or methods for imparting it, as it is concerned with the results of education as determined by individual character. That is to say, it appears to be rather in its character-forming efficiency than as to its content or method that our educational system falls short of what it should be.

There must always be different educational methods and systems, because of the wide diversity of pursuits in human activity each demanding a different sort of training for the successful accomplishment of its respective end; yet, notwithstanding the almost unlimited variety of objects for which it is the purpose of education to prepare those who are to undertake their attainment, there are nevertheless certain fundamental elements common to the purpose of all departments of education, lacking which they are to that extent defective and therefore incapable of properly fulfilling their purpose, whatever that purpose in particular may be. These essential elementary factors are all those means and methods which have for their object the development of the inherent resources of the individual to an extent that makes him master of those powers that are his natural endowment, and which in their sum total when developed constitute the thing called character. Or, stated in the language of physics, it is the function of education to render kinetic the potential endowments of the individual and to express them in terms of efficiency. Human nature is complex, whether studied *en masse* or individually, yet the ever-increasing tendency to specialization—growing as it does out of the very nature and necessities of our modern forms of social organization—seems to justify if it does not necessitate the one-sided educational development of the individual; hence it is that in fitting our educational systems to our social demands we apparently ignore the fact that we are in some degree crushing out individualism and originality, qualities that manifest themselves only at their best when all of the latent or natural individual powers are developed; and this is done by over-training certain faculties while correspondingly dwarfing others.

In dentistry we struggle unceasingly in our educational processes to reduce the mass of data with which we have to deal to something like order and system. We do this not only with our

science, but with our art as well. We seek for the common chord, the underlying principle, and to this we relate our data so that we may find and use them just as we card catalogue specimens, tools, or book accounts. Were it possible to do this absolutely, to reduce our art and its governing science to a final and complete system, there would seem to be no good reason why the practice of dentistry should not become as automatic as that of mechanical piano-playing. But there is, through it all, the great variant factor of vitality with its protean manifestations, which always introduces the unknown element into the problem—and the unknown element always demands originality for its interpretation; hence it is that no mere automatic routinist in dentistry can ever fully measure up to the demands of his calling. Dentistry demands flexibility of resource, originality, constant adaptability to ever-changing conditions, and the ability to successfully meet new conditions as they arise. These are qualities which our educational system should develop, and develop abundantly, if coming generations of dentists are to be made worthy of their high vocation.

Our present methods of education do not develop the qualities above referred to as they should do, and it is difficult to see how under existing conditions any decided improvement is to be brought about; difficult, because the whole machinery of dental education is lacking in the type of originality that is capable of practically acting upon the ideal that the function of dental education is to make the best dentist. We have copied our system from the kindergarten and from medical educational methods, and have produced a mongrel blend of the two, but our fundamental fault is that we are not training men to think; on the contrary, we are doing their thinking for them and training them to memorize the result. Education is not merely memory training. A well-developed memory is an essential part of the mental equipment of all normal individuals; it is particularly valuable to the practitioner of any department of the healing art; but there is such a thing as over-training the memory at the expense of other equally if not more important faculties—packing the mind with a mass of data to a degree that destroys the power of original and independent thinking. Our whole educational system tends too strongly in the direction above indicated; we seem to

be systematically minimizing the power to reason by emphasizing the ability to memorize, and we test the result by an examination system addressed almost exclusively to the memory rather than to the reasoning faculty.

In the *Lancet* for March 2d there is published an address by Dr. Lauriston E. Shaw, on the "True Aim of Medical Education, and the Evil of the Examination Fetich," which while decidedly unorthodox—indeed, almost revolutionary from the standpoint of the present educational system in medicine—is nevertheless so sanely written and so full of wholesome reasoning that it cannot fail to have its effect in ultimately correcting some of the evils which it criticizes. Dr. Shaw clearly points out the evil effect upon the minds of both teacher and student of the "external examinations" system, by which the student is subjected to an examination by authorities to whom he is known only as a number and who have no knowledge whatever of his personal characteristics nor of the sort of intellectual training through which he has passed. Preparation for the external examination absolutely necessitates the cramming of the memory with all the data from which the limited number of set questions may be selected by the official examiner. The effect of such a method is pernicious not only for the student but for the teacher, who instead of devoting his time and energies to the training of his pupils in the direction of observation and correct reasoning about their work, is compelled to aid and abet in the memory-cramming process and devote too much of his time to furnishing examination tips to enable his pupils to obtain the necessary pass.

Dr. Shaw very truly says in this connection, "What we must aim at turning out of our schools is not the man primed with a complete knowledge of all possible beliefs held by his various examiners at the date of his qualification, but a man capable of criticizing these beliefs with sound judgment even if he has never heard of them before. We must turn out men sufficiently interested in their science to watch with an even mind the shattering of these beliefs by its progress and able to estimate the value of others introduced to take their places. . . . Nothing has been more depressing in recent years than the progress of the idea that a special race of researchers must be bred to advance medical knowledge—men who are to be freed from the

routine of education or practice, safely shut away in their laboratories from students and patients, and prepared for their incarceration by a period of special study, preferably in Germany. . . . To encourage men's powers of research, . . . the power of learning from everyday facts, must be our constant aim. This power exists in every sane human being at birth, and it is the chief condemnation of most modern education that it tends to strangle instead of cultivate it. If we could stop the strangling process so far as medical education is concerned, and turn out all our students able to learn from what they see, the result on the progress of medical knowledge would indeed be satisfactory. But, apart from enabling him to take his share in the general advancement of science, every private practitioner needs for his personal service to the individual patient a high development of his powers of observation and deduction. For the diagnosis of any case no amount of mere fact-knowledge will avail the man who has not trained his eyes, ears, and fingers, as well as his brains, in a way not demanded in the pursuit of examinational success. This fact is indicated by the common observation at the hospitals that the best man at examinations often turns out the worst in the house appointments."

The constantly increasing volume of facts with which the student is concerned and must have at his command in preparation for examination is continually operating in the direction of intensifying the memory-cramming feature of our educational systems, and correspondingly tending to crush out those elements of intellectual activity upon which original research as well as real success in practice is based. The evils of which Dr. Shaw complains we believe to be real and important; they constantly present themselves in various aspects to the minds of those engaged in teaching work, and they are evils which sooner or later must be definitely reckoned with and corrected. It is difficult to suggest detailed methods by which a reform in these matters is to be brought about, but it is quite evident that when our ideal of education is the development of reason, and when we work with that ideal as our objective goal, we shall make greater progress and produce a more efficient type of practitioner, as well as a greater number of scientific researchers, than at present with the examination ordeal as the principal goal of our educational effort.

REVIEW OF CURRENT DENTAL LITERATURE.

Conducted by JULIO ENDELMAN, D.D.S.

A CASE OF SEVERE HEMORRHAGE FOLLOWING THE EXTRACTION OF A LOWER MOLAR: TREATMENT. BY ALBERT CANDAU, CHIEF OF CLINIC AT THE ÉCOLE DENTAIRE, BORDEAUX.

Hemorrhage is one of the serious accidents that may follow the extraction of teeth. Dr. Moreau of Paris, who had made a conscientious study of the question, reported already in 1873 twenty-six fatal cases brought about exclusively by post-extraction hemorrhage. Since that time the list of such accidents has been greatly increased, both in Europe and in the United States, as evidenced by the reports published at relatively frequent intervals in the lay, medical, and dental periodicals of these countries. The case reported by Mr. Candau was that of a male adult, for whom the author extracted a lower left third molar under two per cent. stovain anesthesia. After the extraction the alveolus was washed out with a weak, warm thymol solution and with a three per cent. hydrogen dioxid solution. Upon leaving the office the flow of blood from the alveolus had practically ceased. Eight days afterward the patient called again, this time on account of severe pain from which he had been suffering since the day before, and which was doubtless caused by a loose, badly decayed, and broken-down right second molar. The tooth was extracted without the previous use of an anesthetic, inasmuch as the looseness of the organ in its alveolus foretold the easy and uneventful operation which the extraction proved to be. The alveolus was treated as in the previous case, and the patient dismissed. On the morning following the extraction the patient again sought the services of Mr. Candau for the relief of a hemorrhage from the alveolus of the second molar, which lasting as it had since the previous evening, and having resisted the treatment prescribed by the physi-

cian called in during the night, had weakened him almost to the point of exhaustion. After having ascertained that the alveolus was free from spiculæ of bone, and realizing the importance of an immediate intervention on account of the debilitated condition of the patient after about seventeen hours of continuous loss of blood, the essayist proceeded in the following manner: After saturating a tampon of absorbent cotton first with tincture of benzoin and then with sandarac varnish, he carried it to the alveolus and adapted it tightly at the apex and sides. An additional tampon was placed upon the first one, of such dimensions that when the jaws were brought together a reasonable degree of pressure would be exerted upon the alveolus. Even prior to the application of the second tampon, the hemorrhage had practically ceased. To prevent the displacement of the tampons a bandage holding the jaws immovable was applied; this was removed some hours afterward, at which time the hemorrhage had been completely arrested.

The patient was not a hemophilic. No member of his family had ever suffered from this disturbance; he had passed the age at which the manifestations of hemophilia are frequent, and in addition neither a number of wounds which he had suffered in the course of his life, nor the extraction eight days previously of a third molar solidly set in its socket had given rise to any undue loss of blood. The patient had never suffered from epistaxis, a symptom of hemophilia, and showed complete absence of spontaneous ecchymoses or petechiæ, both stigmata of hemophilia. On the other hand, it is well known that certain intoxications, i.e. alcoholism and such disturbances as albuminuria, nephritis, rheumatism, cardiac disorders, etc., predispose to hemorrhage, but none of these conditions had at any time existed in this patient. A careful consideration of the clinical history and the fact that the hemor-

rhage was arrested through mechanical means led the writer to conclude that it had been caused by the rupture of an aneurysm of the inferior dental artery.

BRUXOMANIA (GRITTING OF THE TEETH). BY DRS. MARIE AND PIETKIEWICZ.

Under the term "bruxomania," the authors designate the habit of gritting the teeth as observed in patients having a lesion or some definite alteration of the central nervous system, either temporary or permanent. Bruxomania should be differentiated from mandibular trismus, inasmuch as the latter is brought about by a spasmodic contraction of the elevators of the lower jaw, and cannot be overcome ordinarily either by a voluntary effort on the part of the patient or by outside force. Gritting of the teeth, on the other hand, brings into play a greater number of muscles—practically all the muscles of mastication—and is arrested after a certain time either through a spontaneous effort on the part of the patient himself or following the emphatic command of another person. Neither does bruxomania, properly speaking, refer to the involuntary grinding of the teeth that is apt to occur in the course of such acute cerebral diseases as meningitis of the base of the brain or of those general diseases, such as nephritis, which induce systemic intoxication involving the cerebrum; it refers only to those cases of gritting of the teeth in which the act is the result of some lesion in the cortex, probably in the neighborhood of Broca's region in the ascending frontal convolution. Bruxomania has been observed in paralytics at any stage in the evolution of the disturbance, in the third period of spasmodic hemiplegia of infancy, in dementia, epilepsy, chorea, in Little's disease, etc. In all these disorders it is invariably associated with disturbances of speech, aphasia, and with monoplegia of some form. Bruxomania appears spontaneously, and the sound caused by the gritting and grinding of the teeth is occasionally of such volume as to interfere—in the case of hospital patients—with the sleep of those in adjoining cots. Some bruxomaniacs grind their teeth for only a few moments each day; others for entire days, weeks and months, and still others do

not cease even during sleep. In some cases it ceases and disappears spontaneously, and in others it persists until death. Bruxomania which has lasted for several years brings about characteristic lesions of the teeth. All the teeth are worn down flat, appearing as if ground with a stone wheel. The anterior teeth, in particular, are occasionally worn down almost to the gingival margin. The authors, after a long and painstaking clinical observation, report upon twelve cases of disorders of the central nervous system in which bruxomania developed. Among those cases there were two of general paralysis; one of Little's disease; two of dementia; one of organic dementia complicated with right hemiplegia and transitory aphasia; one of intellectual debility due to chronic alcoholism; one of general paralysis complicated with intellectual debility and absence of self-consciousness; one of general paralysis with embarrassment of speech; one of senile paralysis with embarrassment of speech; one of general paralysis in the later stages, and one of general paralysis with complete speech interference.

A REVIEW OF THE "MANUAL ON THE ART OF THE DENTIST" BY JOURDAN AND MAGGIOLLO (PUBLISHED AT NANCY, JANUARY 1807). BY B. PLATTSCHICK, PARIS.

Dr. Jourdan, of the faculty of medicine of Montpellier, and M. Maggiolo, surgeon-dentist of the faculties of Genoa and Pavia, published in January 1807 a work in French entitled "*Manuel de l'Art du Dentiste*," in which they discuss the manner of preserving the teeth in good condition, the mechanical improvements discovered by Maggiolo, and some practical suggestions on the use of artificial teeth, their manufacture, etc.

This manual is, in the opinion of dental historians, the best work on dental technics written in the French language up to the time of its appearance and for many years thereafter. Carefully prepared and containing a considerable amount of interesting and valuable information on dental prosthesis, the manual was to be found in the hands of practically every dental practitioner of the time. Throughout the book the authors furnish ample evidence of a

thorough comprehension of the rôle and function of the teeth, and "deplore that during the eighteenth century—a century of enlightenment—so little should have been done toward the preservation of the teeth—organs indispensable for a thorough mastication and consequently for good digestion; organs which to a large extent contribute to the beauty and sonorousness of the human voice; organs which prevent the occurrence of buccal affections, the alteration of the breath, and even those diseases of the chest too frequently caused by carious teeth."

Being anxious to remedy this condition of things, they prepared the manual, whose essential purpose was to make good practitioners of dentistry by teaching dentists in detail how they themselves might construct all the varieties of artificial teeth in use at that time.

They express themselves in favor of preserving the roots of teeth by such means as fumigations with pyrethrum (pellitory) or calamus (sweet-flower), and by the introduction of opium seeds from time to time into the carious cavity. If after three or four days of such treatment the tooth fails to recover, the operator may resort to extraction. For the performance of this operation they recommend Garengnot's key, and condemn the pelican.

Considering the otherwise progressive and practical tendencies of the authors, it is astounding to find that they were most emphatically opposed to the use of porcelain for prosthetic purposes. They admit that it is possible to imitate the exact contour of the gums, but such substitutes never fit accurately, owing to the contraction of the porcelain.

"It is necessary," they say, "for those having to wear porcelain dentures to exercise an unusual degree of patience," and in support of this opinion quote Gariot, who although a strong partisan of porcelain, avows that it requires about six months for a patient to become so accustomed to a denture as to enable him to masticate with facility. In addition, they claim that the denture cannot be tried in until after the piece is removed from the furnace, and that the porcelain paste does not imitate the natural teeth as accurately as does the ivory of the hippopotamus and of the sea-horse. Therefore Jourdan and

Maggiolo aver that they will never employ porcelain.

A very important chapter of the book is the one in which the preparation of the base upon which the artificial teeth are to be supported is described. After unfavorably criticizing the methods then in vogue, they recommend and describe as the first step of the operation the obtaining of an impression of the mouth with wax. Although M. Platschick does not make any further allusion to the history of the introduction of wax and plaster for obtaining impressions of the mouth, it may not be considered amiss to recall in this connection that it was Philip Pfaff, dentist to the King of Prussia, who in his work on odontology, published in 1756, referred for the first time to wax and plaster impressions; and that some time prior to 1756, Geoffroy Purmann was the first to avail himself of plaster for the same purpose.

In the chapter of the manual devoted to pivot teeth, a description is to be found of a method of crowning which, in the main, consists of fitting a tube in the root-canal intended to receive the pivot of the crown substitute—the crown of an extracted tooth—to which the pivot is attached by means of a small piece of gold plate riveted at the lower extremity of the pivot, and within a transverse groove on the lingual surface of the crown. In addition, they recommend, instead of the plain vertical pivot, one made by bending a piece of wire upon itself in such a fashion that when one end is embedded in the crown and the other left free, the pivot will have sufficient springiness to hold the crown in place, while at the same time allowing for its removal whenever necessary without unduly straining the root.

Jourdan and Maggiolo also recommend implantation of artificial tooth-roots in cases in which the original root is so loose and broken as to preclude the possibility of its supporting an artificial crown. "Extract the old root, and introduce into the alveolus an artificial root. A month later attach a pivot tooth to the root." They feel that this operation may be considered as one of the most beautiful within the art of the dentist, offering precious advantages and giving satisfactory results.

The authors devote several chapters to the process of making full dentures, and in this connection express themselves in favor of re-

taining such roots as may remain in the mouth. They call attention to the valuable services that these roots may be made to render, and condemn the use of metallic bands fitted around teeth for the support of dentures, as such teeth soon become loose and their necks exposed, owing to recession of the overlying gum tissue. They likewise speak unfavorably of the type of springs then in use for the retention of full dentures, saying that their presence prevents the opening of the jaws to the normal extent, and consequently the proper and thorough mastication of food, which under the circumstances becomes painful. Also, that they interfere with speech, and that their presence in the mouth makes their wearers hesitate even to sneeze or to blow their noses. The authors remedied all these inconveniences by devising a spring which obviated all of the above-mentioned disadvantages.

TUBERCULOSIS OF THE MUCOUS MEMBRANE OF THE MOUTH. BY DR. BERNSTEIN, COPENHAGEN.

Tuberculosis of the oral mucous membrane is but rarely observed. It may occur in the course of pulmonary tuberculosis, or as a primary infection. The ectogenous form attacks most frequently the nasal mucous membrane; while the endogenous form attacks the mouth and throat. The latter occurs with greater frequency than the former, which as a matter of fact may be considered in the light of a medical rarity. Petit mentions a case of primary tubercular infection of a retro-maxillary gland. Another case was that of a man with primary tubercular infection of the submaxillary gland and pharyngeal lymphatics. Scholl mentions a case of labial tuberculosis in a man otherwise free from the disease.

Regarding cases of secondary infection, Jaruntowski mentions the case of a consumptive in whom an ulcer developed in the mucous membrane posterior to the lower left third molar, which eventually involved a considerable area of mucous tissue. The molar was decayed, and the cavity was found filled with debris rich in bacilli tuberculosis. Jaruntowski reached the conclusion that the infection had originated from the cavity of de-

cay. As a rule, however, most cases of buccal tuberculosis occur as a secondary manifestation in consumptive patients. The author himself has observed the following two cases:

Case I was that of a patient thirty-seven years of age, presenting a granular infiltration of the mucous membrane in the vicinity of the upper left canine. The inflammation spread following the extraction of several teeth, and was doubtless secondary to pulmonary infection.

Case II was that of a young woman twenty-one years of age, who presented an ulcer of six years' standing in the labial mucous membrane. The ulcer had not been previously treated, as it did not in the least inconvenience the patient. Lately, however, the infection having spread, it has involved the cheek, which appears swollen and contains an infiltration of the size of an ordinary bean. It did not present the characteristic granular appearance of tubercular infection, although the specific bacillus was isolated from the ulcerated area. Thus far treatment with hetol injections, lactic acid, Finsen light, etc., has failed to relieve the inflammatory phenomena.

[*Lancet*, London, November 3, 1906.]

A CASE OF ACTINOMYCOSIS OF THE CHEEK CURED BY POTASSIUM IODID; WITH SUGGESTIONS AS TO THE POSSIBLE MEANS OF INFECTION AND SPREAD OF THE DISEASE. BY ROBERT KNOX, M.D., M.R.C.S., ETC.

After calling attention to the importance of an early diagnosis in actinomycosis, the author reports the case of a child aged seven and a half years, who in little less than a year's time completely recovered from an attack of actinomycosis of the cheek, under gradually increased doses of potassium iodid until a maximum of gr. xlix per diem was reached. The swelling of the right cheek was situated midway between the mandible and the maxilla, and was of about the size of a small walnut and was irregular in outline. Small areas of softening could be detected on digital examination, and semi-fluctuation could be elicited on carefully palpating the swelling with one finger in the mouth and the other on the cheek. At these points the cutaneous surface was greatly thinned out and presented a bluish-red color. When first

seen there were several places on the surface where the inclosed pus tended to point, and a thin crust was already forming over these points. On carefully examining the buccal mucous membrane several small abrasions could be detected, and it was obvious that the infection had originated at these points. The abrasions had been caused by two lower molars which were in a state of advanced decay and had very rough edges. The patient presented such constitutional symptoms as rapid pulse, 104 per minute, and a temperature in the evenings of 104° F. The child had lost weight, was very lethargic in her movements, and complained of feeling tired. Suspecting the nature of the disease, Dr. Knox opened the abscess, and the typical granules were seen in large quantities. One of these was teased out in water, and showed on microscopic examination the mycelium of the fungus. The treatment consisted in the removal of the diseased teeth, the use of an antiseptic mouth-wash, the application of hot boric fomentations on the cheek, and the internal administration of potassium iodid, as above stated.

Concerning the way in which the parasite gains entrance into the body, the author believes that while in some cases it is carried on straw or grain, in other cases the method of infection remains a mystery. It is sometimes communicated by direct inoculation from one individual to another, while there are cases on record in which the disease was acquired through the consumption of infected meat. To the eradication of the latter source of infection the larger share of prophylactic measures should be directed.

[*Revue Odontologique*, Paris, February 1907.]

DENTIFRICES. BY DRs. CARLE AND PONT,
LYONS, FRANCE.

In the course of their investigations on the composition and properties of tooth-powders, the authors (*Le Monde Médical*) have found that salol, which, as is well known, has been repeatedly incorporated in tooth-powders, exercises such detrimental effects upon the lips and soft tissues of the mouth as to render it in this connection both useless and injurious. They have collected five cases in which perilabial eczema was arrested, and eventually cured by the elimination of salol

from the tooth-powders that were being used by those so affected.

Drs. Carle and Pont then take up the question of the sterilization of the human mouth, and reach in this connection conclusions which are entirely in accord with the opinion of the reviewer, namely, that the use of purely therapeutic agents in the attempt to sterilize the mouth is a procedure of questionable efficacy, inasmuch as the results are lasting only in proportion to the frequency and thoroughness with which such agents are employed. Whatever beneficial results are obtained from the use of solid or liquid dentifrices must in the main be attributed to the degree of mechanical action used in connection with them, and not to the disinfectant or germicidal properties of their ingredients.

In the opinion of the essayists a good dentifrice is the one which in addition to exercising a mechanical action, thus freeing the teeth from all deposits of extraneous matter, will neutralize the acid end-products of carbohydrate fermentation. Finely prepared chalk, magnesium carbonate, and sodium bicarbonate—faintly or not at all aromatized—constitute the simplest and best dentifrice ingredients. They may be combined in a formula as follows:

Magnesium carbonate,	3iij;
Calcium carbonate,	3iij;
Oil of peppermint,	gtt. x.

[*British Dental Journal*, London, March 1, 1907.]

A CASE OF REPLANTATION. BY MR. FREDERICK LONNON.

The author reports the case of a boy aged sixteen, who was struck in the mouth by a ball while playing cricket. The impact of the ball forced out the upper right central incisor, which, after lying upon the ground for about an hour, was taken to Mr. Lonnnon, who after placing it in a mercury bichlorid solution removed the pulp, filled the root-canal and pulp-chamber, syringed the socket with a 1:2000 mercury bichlorid solution, and then replanted it. On the day after the replantation a splint embracing the adjoining teeth was cemented; this was removed three months afterward. The tooth, which has now been *in situ* for six months, is in perfect condition.

PERISCOPE.

Mouth-wash for Thrush in Infants.—

R—Potassium chlorate,	4 gm.
Distilled water,	200 "
Tincture of myrrh,	3 "

Sig.—Use as a mouth-wash.

—*Vierteljahrsschrift für prakt. Pharmacie.*

To Locate the Irritating Portion of a Plate.—As it is sometimes difficult to locate just exactly the irritating spot of a plate, place with a spatula a little wet whiting about the locality of the trouble, put the plate in position, and the precise spot will be readily seen.—L. P. HASKELL, *Dentist's Magazine*.

Rusting of Iron.—Dr. Gerald T. Moody has contended that iron cannot rust in the absence of carbon dioxid, but Dunstan has repeated the experiments, and the results show that iron rusts freely in the absence of carbonic acid, provided that iron, oxygen, and liquid water are brought together.—*Chemist and Druggist*.

Mouth-wash for Syphilitic Ulcers.—

R—Hydrarg. chlorid. corrosiv.,	0.2 gm.
Alcohol,	2 "
Tincture of myrrh,	100 "
Decoction of cinchona,	150 "
Honey of rose,	45 "

Sig.—Use two or three times a day as a mouth-wash.

—*Vierteljahrsschrift für prakt. Pharmacie.*

Remaking a Plate Without a New Impression.—Make a model by sticking all the pieces together with sealing-wax. Then the plate is invested in the ordinary way in the flask. When the plaster has set, the sealing-wax holding the pieces together is removed, and a thin coating of beeswax is placed over the old rubber plate to make allowance for scraping and polishing. When this is done the old plate, teeth, and surrounding plaster are freely coated with oil. The upper half of the flask is then filled with plaster. It is allowed to stand only about ten or fifteen minutes, so that the plaster should not set too hard around the teeth. The flask is then separated by placing the blade of a knife between the parts, leaving a nice impression of the teeth in the

plaster of the upper half of the flask. The lower half of the flask, containing the old plate and teeth, is held over a spirit lamp, when the teeth are easily removed, and are replaced in their respective positions in the plaster impression in the upper part of the flask. There is no trouble in picking out the old rubber plate when heated. All that has to be done is to pack and vulcanize in the ordinary way.—J. NEELANDS, *Dominion Dental Journal*.

Pointers on Porcelain Inlays.—One of the first essentials in inlay work is to have plenty of room for taking the impression, and I think I need hardly add that there should be no undercuts, and that the edges should be strong and well defined. In a small cavity it is well to make it of a definite shape, so that you will at once recognize the method of insertion when you come to fix it, and thus save yourself considerable trouble. Overhanging edges, if strong, need not be removed, for if there be undercuts the impression may easily be obtained by filling them up with a little gutta-percha, which should be afterward removed.—R. HILL, *Dental Record*.

Calcium Chlorid as a Hemostatic.—Calcium chlorid as a hemostatic is best administered, according to Rosod (*Therap. Monatsschrift*, No. 12, 1906), in the following combination:

R—Calcii chloridi,	gr. lxxv to cl;
Aquæ destillatæ,	℥iijss;
Syrupi menthæ,	℥v. M.

Tablespoonful doses are given during twenty-four hours. In some cases a clyster containing 75 gr. of calcium chlorid with a few drops of tincture of opium is given.—*New York Medical Journal*.

Ichthyol in the Treatment of Pericemental Abscess.—We have all had to deal with those very painful acute conditions sometimes arising in the pockets in interstitial gingivitis—usually those in which no pus is discernible—producing the most intense odontalgia, and often resulting in pericemental abscess. For many years I was absolutely without a remedy for this condition, and when I read an article recommending ichthyol I was very skeptical, as it seemed

rather far-fetched to expect a drug of this kind to relieve pain to any extent. However, having no other remedy, I tried it, and have used it ever since. I do not attempt to explain its *modus operandi*, but can say that in about six years I have never failed to get positive results—almost always immediate and complete relief from the pain; in the cases when the relief was not quite complete, it was nearly so. Ichthyol is a thick fluid, about the consistence of molasses, and with a small flattened silver wire, which can be easily bent and also sterilized in the flame, it is an easy matter to work it into any of the pockets. It is my practice to then paint the gum surrounding the affected root with the ever-ready aconite and iodine mixture. The beneficial effect generally lasts about twenty-four hours, a second application usually being sufficient to bring the pocket to the point where it may be treated radically.—A. J. COTTRELL, *Dental Brief*.

Care of the Plate After Vulcanizing: Avoid Rapid Cooling.—Having vulcanized the piece, do not cool it rapidly if the investment has been of plaster of Paris, because sudden cooling tends to a warping. The writer once caused a vulcanite plate to crack severely by rapid cooling, the investment having been of plaster of Paris hurried into the vulcanizer soon after mixing. Having opened the flask, brush away the plaster adhering to the plate, or if it be very adherent, immerse it for ten or fifteen minutes in fifty per cent. aqueous solution of sulfuric acid. This will soon soften the plaster so that it may easily be brushed away, and will not injure the vulcanite. Hydrochloric acid, however, rapidly dissolves aluminum.—STEWART J. SPENCE, *American Journ. of Dental Science*.

Mouth-wash in Pyorrhea Alveolaris.—The following prescriptions are given in the *Practitioner*:

R—Potassii chloratis, 3ij;
Glycerini boracis, 3v;
Aq. rosæ, ad 3x. M.
Ft. lotio.

If the patient has spongy gums which are liable to bleed readily, the following mouth-wash is recommended:

R—Tinct. myrrhæ, 3ss;
Tinct. krameriæ, 3ss;
Tinct. cinchonæ, 3ss;
Tinct. catechu, 3ss;
Eau de Cologne, 3j. M.

Sig.—A large teaspoonful in a wineglass of water, to be used as a mouth-wash frequently.

Burney Yeo recommends the following as an antiseptic and soothing mouth-wash for adults:

R—Potassii chloratis, gr. lxxx;
Extr. opii liquidi, 3ij;
Aque lauro-cerasi, 3j;
Decoct. hordei, ad 3viij. M.
Ft. lotio.

Or the following:

R—Acidi salicylici, gr. xxxij;
Spts. vini rect., 3iij;
Aq. camphoræ, ad 3viij. M.
Ft. lotio.

Sig.—Dissolve the acid in the spirit and then add the water.

—*New York Medical Journal*.

Amalgam Restorations Better than Gold Crowns.—In restorations involving more than one wall, a band matrix should be used. It can be made either of thin copper or the Angle band material, which comes in different widths. Dr. Clapp of Boston ties and wraps his matrices with a ligature, but I prefer them soldered to fit the case in hand; or I have enough made up of different sizes so that one can be selected to fit. Bands should be firm enough to withstand the lateral pressure of heavy condensation. They should fit as closely as possible at the gingivæ, and yet allow for contact points. An orange-wood wedge will nicely preserve the interproximal space and help to hold the band. If I feel that I cannot obtain sufficient anchorage in the tooth to withstand the probable strain, I set one or more pins in the canals.—GEO. R. WARNER, *British Journ. of Dental Science*.

Method of Obtaining Sticks of "Sticky-Wax" by Casting in Glass Tubes.—Obtain several—say a dozen—lengths of glass tubing. Pieces about one foot long are convenient, but much longer pieces may be used. The tubing should have fairly thick walls. The bore may be of any diameter, though three-sixteenths to one-fourth inch gives convenient sticks of wax. The ends of the tubes should be ground, not melted smooth, as melting lessens the bore at the point of fusion.

Thoroughly clean the tubes and dry the inside by pushing pieces of cotton wool through them. The tubes must then be "lubricated," to prevent the wax from sticking. Do not lubricate with oils. Glycerin forms a very effective lubricant for this purpose, and is easily applied by saturating pieces of cotton wool with it and pushing them through the tubes.

Having the wax melted and the tubes "lu-

bricated," fill each of the tubes as follows: Attach a piece of rubber tubing to one end of a glass tube. Take the other end of the rubber tubing in the mouth. Dip the free end of the glass tube into the melted wax and suck the wax up until the tube is full. Pinch the rubber tubing close to the glass tube, and the tube, full of wax, can then be lifted and laid in a horizontal position. Then release and remove the rubber tubing. The wax will not run out. Repeat the process until all the tubes are filled. When cool, the sticks of wax can readily be pushed out of the tubes. If a piece of wax should stick in a tube, it is either because the tube was not properly lubricated or because its bore was not uniform. I have cast sticks of wax over a yard long by this method. In melting the wax it is better not to use direct heat, but to put the wax in a tin and stand the tin in boiling water. Ordinary pink wax may be cast into sticks for 'waxing up' in the same manner, but owing to the much greater fluidity of pink wax when melted, it is more difficult to manipulate.

The following is a formula for sticky-wax: Pure white beeswax 4 oz., pure light yellow resin 7 oz., pure gum dammar 1 oz., dye q. s. to color. Powder the resin and gum dammar, and add little by little the melted beeswax.—*Dental Record*.

Tooth-Powders.—Tooth-powders and dentifrices were in common use long before tooth-brushes were thought of. Whereas the latter articles were unknown, in England at least, until the seventeenth century, the former were in common use among the ancient Romans. Ovid, who dealt greatly in polite matters—and not a few impolite matters also—gives various recipes for the manufacture of preparations for washing the teeth. As brushes for the teeth were unknown in those days, these dentifrices were applied by means of the bare finger or a rag wrapped around it. Not infrequently a "tooth stick" was resorted to for the purpose. This, usually an orange-wood stick with a small rag around it, came later into general use. In the present day, millions of Hindus and Chinese clean their teeth with small pieces of wood.

Old medical books are very quaint and interesting on the subject of tooth-powders and dentifrices. One gives a very primitive prescription for "a dentifris or powder for the teeth." It says, "Burn a peece of corke till it looke like a coale, then take it out of the fyre, and it will fall to ashes, wherewith rub your teeth." Another recommends "rubbing with a coarse cloth" and finishing up with "a peece of scarlet dipped in hony."

Yet another maintains that there is nothing like pounded china in the way of a good tooth-powder. This tooth-powder is certainly unique, and one is tempted to admit that, whatever its merits, there is indeed "nothing like it." An unlucky wight, mentioned by Surtees, found this out to his cost. It appears that on the way to New York in a coach, he "eat some raisins which in his pocket happened to mix with a dentifrice made of beaten china." This made him so ill that he "had like to die on the road." The maker of such a dentifrice should have labeled it "For the teeth—thus far and no farther." It seems, from this chronicled incident, that it was the custom in those days to carry one's dentifrice loose in the pocket, as the South African does his tobacco.

Another favorite dentifrice of the seventeenth century was water and salt applied with a rag, or by means of a stick made of lentisk, walnut, or liquorice root. Some of these "tooth sticks" were fashioned at one end for use as toothpicks. But in those days it was only the dandies who used a specially made toothpick. Even as late as the nineteenth century we read of Beethoven lying on a couch listening to his own sonatas while he picked his teeth with the snuffers.—*British Journ. of Dental Science*.

Influence of Defective Nasal Breathing on Growth and Development.—Among the functions subserved by the nares in the respiratory process are the heating of the inspired air and the addition of watery vapor, as well as the filtration of particles of solid matter. If this mechanism be deranged from any cause, infection is likely to take place, with resultant catarrhal disturbances and impairment of hearing in case of extension to the Eustachian tube. If nasal breathing be obstructed, especially in children, only imperfect expansion of the lungs can take place, and deformity of the chest results. A certain amount of adenoid tissue is present normally in the naso-pharynx of healthy children, but an excess appears to cause effects apart from the obstruction of breathing to which this gives rise. The mouth-breathing child with adenoids not only presents a dull, stupid look, but also seems intellectually below the average, and is usually stunted in general growth. The improvement in all directions following removal of such excessive adenoid tissue is a most striking and convincing phenomenon. In a discussion of this subject in a recent communication, Dr. P. Watson Williams emphasizes the physiologic importance of the nose in influencing respiratory activity, and the pernicious effect of the absence of the nasal respiration, not alone on account of the

commonly recognized results of unwarmed, unmoistened, and unfiltered air reaching the lungs, but also from the persistent abrogation of nasal respiratory stimulation. At the same time he does not underestimate the factors responsible for the defective physiologic activity of the respiratory centers in children suffering from enlarged tonsils and adenoids, especially chronic sapremia, causing tissue inactivity, and hence absence of the normal need for more rapid respiratory exchanges. Children who persistently fail to expand their lungs fully, or in whom the respiratory exchanges are subnormal, are underfed, for a due supply of inspired oxygen is essential for the utilization of food in the processes of internal respiration. Accordingly, after the removal of abnormal conditions in the nose and throat, it is wise to recommend activity in the open air, cold baths, and particularly physiological drill, comprising appropriate respiratory exercises, in order that the listless, partially asphyxiated child may grow up in the fulness of life.—*Journ. Amer. Med. Association.*

Obtaining Plaster Impression Without the Use of Trays.—In doing this the first thing is to have the patient rinse the mouth with milk of magnesia. This lubricates the teeth, and makes it possible for the plaster to get a close adaptation to the teeth without sticking to them. In taking impressions sometimes the plaster is mixed entirely too thick, and you do not get the fine, nice line you can with thin plaster. If the plaster is mixed so that it will not drop in chunks, but runs off, you can keep on piling up until you have got sufficient surface, so that you will have as much bulk of plaster as you would in an impression tray. But the trouble with an impression tray is that as it is pushed to its seat it almost invariably touches some place, some vulnerable point, and that cuts through the plaster, so that when you take the impression tray away and draw the sections apart, the plaster in many places is so thin that you cannot find the little piece that has broken away, and consequently a hole is left that is nearly always at the wrong point. I feel that I can build up partial impressions very much better without an impression tray than with it. One advantage is this: You can get more bulk of plaster around certain parts of these teeth, and after the plaster has become hard it will not readily move out of place—but still it is easily cut with a spatula or a sharp lancet and removed.—WILLIAM H. TAGGART, *Dental Review.*

What Gold Foil Annealing Really is: the Advantages of the Electric Annealer.

—It is well known that there is little difference between cohesive and non-cohesive gold as it comes from the manufacturers, except that the non-cohesive has ammonia gas condensed on its surface. Both are purified, beaten, and annealed in the same manner, but just previous to marketing, a part of the lot is passed through ammonia fumes and marked non-cohesive, simply because the fumes form an imperceptible film which, while not affecting the purity of the gold itself, prevents intimate cohesion of the different layers of gold. From this we may see that a pellet of cohesive gold may be made non-cohesive by exposing it to the influence of ammonia gas, and this pellet thus rendered non-cohesive may in turn be made cohesive by driving off the gas with heat. This latter process is what we actually accomplish in our everyday operations with non-cohesive foil when we heat it, and it is in no way intended to anneal the gold.

The so-called "annealing" of gold foil is not analogous to, nor in any way connected with, the annealing of plate gold which has become hard by hammering, and which has to be raised to a red heat to relieve it of the state of strain. Much of the difficulty experienced by operators in the insertion of gold is undoubtedly due to faulty methods of giving it the heat treatment, and even among operators who are sufficiently skilled to obtain good results by the ordinary methods, there is much to be gained by adopting some of the more recent advantages that are offered us in the use of the so-called "electric gold annealer." Most operators are in the habit of heating their gold by passing it through the flame of a spirit lamp, or a Bunsen burner, but in either instance we are never certain of always having a pure flame; besides, there is not one in a dozen that understands that he is removing gases, and not developing cohesion, which is an inherent quality of the pure clean gold itself. To remove these gases uniformly and completely, a comparatively low heat and more time is required, and this is best accomplished with an electric annealer. It has been shown by experiment that the cohesive property of ordinary gold foil as it comes from the manufacturers shows itself at about 250° F., after which nothing is gained. As this heat is not visible, many dentists who have not tried the gold annealer with its low heat believe that the gold annealed in this way is not thoroughly annealed, but clinical use shows it to be most cohesive.—M. C. WARD, *Dental Register.*

HINTS, QUERIES, AND COMMENTS.

METHOD OF REPLACING A FACING ON AN ANTERIOR BRIDGE.

THIS is a very simple but effective method of replacing a facing in cases where it has been broken off, leaving the pins intact within the metallic portion of the bridge. Let us take as an instance an anterior bridge from canine to canine, where a facing has been broken off. Having a napkin and cotton roll in place to keep the parts dry, and making sure that the pins are straight so as to permit the removal of the matrix, platinum 1:1000 is pressed into place over the pins by means of a piece of rubber. The matrix is then burnished into the position occupied by the lost facing, care being taken that it is burnished laterally over the adjacent teeth far enough to serve as a guide for the necessary contour. Care should also be taken to have a slight projection of the matrix at the incisal edge, and at the cervical margin the matrix should touch the gum and be trimmed in alignment with the other teeth, or as the case may indicate.

The matrix being fitted we are now ready to add the porcelain. The Parker body is best suited for this work, on account of its easy manipulation—it being of a putty consistence—as all these steps are done in the mouth. When the desired contour and length are obtained, the piece is removed and bisected. The porcelain in this state being like chalk, the holes for the pins may be slightly enlarged in it with a small round bur, to allow for the easy readjustment of the matrix. The enlargement of the holes for the pins also allows for the shrinkage in the final baking.

The matrix is readjusted and the enamel added, after which it is placed in the oven and given the final baking. When cool, remove the matrix from the facing, and after etching the porcelain with hydrofluoric acid—which can best be done by pressing the facing labial side downward into beeswax up to the margins—the facing is ready to be set. Before

setting, however, it is well to roughen the gold by means of a bur or excavator, in order to secure better adhesion for the cement. Ordinary cement may be used. The advantages of this method are that the work is all done in the mouth, in a comparatively short time, and at one single sitting.

L. A. WHITE.

*Harvard Univ. Dental School,
Boston, Mass.*

TO SECURE DRYNESS IN LABIAL CAVITIES.

To prepare and fill cavities in labial surfaces of the six upper anterior teeth, place a cotton roll under the lip directly over the root of the tooth to be filled, then cut a piece of silk floss about twenty-four inches in length, double it upon itself, and tie the ends together. After having placed the floss over the tooth, and drawn it well up against the lingual surface, pass the silk over the patient's face, allowing it to rest upon the cotton roll and lip, and with a weight on the other end of the string, let it fall over and behind the patient's head. This, with a little help on the part of the patient, will enable one to fill all such cavities without the use of the rubber dam, very much to the satisfaction of the patient as well as that of the operator.

E. S. RICHARDS.

Hope, Ark.

PREPARATION OF MATRIX FOR CAVITIES EXTENDING UNDER THE GUM.

DOUBTLESS all inlay workers have experienced trouble in getting the matrix to cover the cervical border of the cavity, especially when situated above the gum line. This can be readily overcome by cutting the gold to the proper shape, and then turning the upper margin over about one-sixteenth of an inch or less.

Hang the matrix by means of the fold thus produced on a fine silk thread, and press the fold down so that the thread and gold can be carried to place, in order to use the thread as a binder to hold the matrix in place. After burnishing the matrix to position, cut one end of the thread near the gold and draw the other end out. This arrangement reinforces the upper margin and prevents bending the matrix during its removal from the cavity. Try it once and you will find it indispensable.

T. S. PHILLIPS.

Buffalo, N. Y.

AN INTERESTING CASE IN PRACTICE.

Mrs. M., age thirty-seven, was cured of headaches and relieved of the necessity of wearing glasses, after the extraction of a tooth which was the seat of an abscess. She had suffered for nearly two years from severe headaches accompanied with an im-

pairment of the right eye, and had been wearing glasses for over a year, which partially relieved the condition.

She came to me to have an upper right central incisor treated on account of its discoloration. I opened into the tooth and found the root-canal filled with cotton. Upon the removal of the cotton there was a discharge of pus, and by instrumental examination I found the apical third of the root to be softened, and also found a large opening beyond, together with some destruction of the alveolar process. I advised immediate removal of the tooth and curettement of the alveolus, which I did under nitrous oxid. The opening was packed with aseptic gauze for a few days, and then allowed to heal. The headaches disappeared, and the glasses were discarded within a month. Two years later I saw the patient, and there had been neither recurrence of headaches nor impairment of eyesight.

LEGRAND M. COX.

St. Louis, Mo.

OBITUARY.

DR. J. HALL MOORE.

DIED, of heart failure, at Richmond, Va., December 28, 1906, J. HALL MOORE, M.D., in his seventy-fifth year.

Dr. Moore was the son of James Moore, who came from the north of Ireland in 1800, and was one of the first settlers of Washington, D. C., at which place Dr. Moore was born in 1832. Dr. Moore studied dentistry for five years with Drs. Luther Parmele and William Malster, and in 1853 began the practice of his profession. His medical education was received at Georgetown University. While holding a position in the U. S. Treasury Department, he employed his leisure hours in practicing dentistry as the opportunity presented, yet much of his time during those four trying years was spent in field and hospital work. Resuming his office duties after the close of the war, he soon became one of the leading practitioners of the city of Richmond, to which place he had moved his residence in 1861, his *clientèle* be-

ing composed of the leading citizens of that place. Being deeply interested in his profession he was among the first to participate in everything that looked to the elevation of dentistry. In the state dental association he was one of the leading spirits, serving as president for three successive terms.

In the making and framing of the state dental law he was a most active participant, and after the passage of the law served ten years as president of the State Board of Dental Examiners. For six years he held the position of professor of clinical surgery in the Dental Department of the Medical College of Virginia, and for four years was chairman of the dental faculty.

While thus engaged in all the activities of life, chief and uppermost with him was the obligation that he was his brother's keeper, and by his godly life and conversation he stood forth as a living epistle, known and read of all men. By his good works and deeds many will at the last day rise up and call him "blessed."

The Richmond City Dental Society, at a meeting called for the purpose, passed the following resolutions of regret:

RESOLVED, That in the removal of Dr. Moore we have indeed lost the companionship of a true and loyal friend, the counsel and advice of one who was truly prepared by long and varied experience to lead most cheerfully, as he did, those of fewer privileges, and that our society has been deprived of the services of one of its most useful members—one whose noble character entitled him to the love and admiration of all; and be it further

RESOLVED, That we tender to his family our sincerest sympathies in their great affliction, and that a copy of these resolutions be sent to the family, and to the dental journals and daily papers for publication, and that they be spread upon the minutes of this society.

DR. ALONZO H. STEVENS.

DIED, at his home on High street, Clinton, Conn., December 15, 1906, Dr. ALONZO H. STEVENS, in the sixty-eighth year of his age.

Dr. Alonzo Hiel Stevens, a son of the late Hiel Stevens, was born in Clinton, Conn., June 22, 1839. He was educated in the public schools of his native town, and before the age of twenty went to New Haven, where he entered upon the study of dentistry under the direction of a relative, Dr. Henry Stevens, who still remains a resident of that city. Soon after completing his apprenticeship he enlisted, October 26, 1862, in Company A, Twenty-seventh Regiment, C. V., and was honorably discharged from service, with other members of the company, July 25, 1863. He soon afterward entered upon the practice of dentistry in Clinton, where he remained uninterruptedly until the time of his demise.

Dr. Stevens, although not an aspirant to public office, was for several successive years a member of the town board of education. In addition to his fondness for mechanical pursuits he was a student of natural history; but in none of his avocations did his degree

of skill and ingenuity exceed that which he displayed in the work of his chosen profession, for here to the last he kept abreast of the times in every detail.

Dr. Stevens married a daughter of the late John R. Farnham of Clinton, his wife surviving him, together with three sons, John F., Alfred H., and Robert H. Stevens, all of whom are engaged in business in New York city.

DR. SAMUEL J. McDougall.

DIED, at Jamaica Plain, Mass., February 8, 1907, SAMUEL J. McDUGALL, M.D., in the seventy-seventh year of his age.

Dr. McDougall was born in Albany, N. Y., June 29, 1830. After obtaining a sound preliminary education he entered upon the study of medicine, graduating from the Albany Medical School in 1857. Shortly afterward, having been attracted to dentistry, he took up that study in Boston for a short time, eventually acquiring the practice of Dr. Kendal, a dental practitioner of that city.

Dr. McDougall was well known in medical circles throughout New England. It was largely through his efforts that the Massachusetts Dental Society was organized in May 1864. He was a member of the New England Dental Society, the Massachusetts Medical Society, and the Albany Medical Society, and at one time professor of dental therapeutics in the Boston Dental College. He retired from active practice in 1900, and soon afterward went to live with his daughter, Mrs. Arthur G. Brigham of Colorado Springs, Colo. He had, however, been making his home since April 1906 with his daughter, Mrs. Charles M. Lawrence of Jamaica Plain, Mass.

On May 2, 1860, he married Miss Elizabeth Miller of Albany, N. Y. Three daughters survive him, Mrs. Charles M. Lawrence of Jamaica Plain, Mass., Mrs. Wilmot S. Haskell of Boston, Mass., and Mrs. Arthur G. Brigham of Colorado Springs, Colo.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS:

May, June, and July, 1907.

MAY.

ALABAMA DENTAL ASSOCIATION. Birmingham. Four days: May 14th to 17th.
ARKANSAS STATE DENTAL ASSOCIATION. Eureka Springs. Three days: May 29th to 31st.

EASTERN INDIANA DENTAL ASSOCIATION. Anderson. Two days: May 14th and 15th.

GEORGIA STATE DENTAL SOCIETY. Atlanta. Four days: May 7th to 10th.

ILLINOIS STATE DENTAL SOCIETY. Quincy. Four days: May 14th to 17th.

IOWA STATE DENTAL SOCIETY. Cedar Rapids. Three days: May 7th to 9th.

KENTUCKY STATE DENTAL ASSOCIATION. Louisville. Three days: May 20th to 22d.

LAKE ERIE DENTAL ASSOCIATION. Cambridge Springs. Three days: May 21st to 23d.

MISSISSIPPI DENTAL ASSOCIATION. Meridian. Three days: May 28th to 30th.

NEBRASKA STATE DENTAL SOCIETY. Lincoln. Three days: May 21st to 23d.

NEW YORK STATE DENTAL SOCIETY. Albany. Two days: May 10th and 11th.

ODONTOTECHNIQUE SOCIETY OF NEW JERSEY. Newark. May 4th.

OREGON STATE DENTAL ASSOCIATION. Portland. Three days: May 9th to 11th.

SIXTH DISTRICT (NEW YORK) DENTAL SOCIETY. Binghamton. Two days: May 2d and 3d.

SOUTH DAKOTA STATE DENTAL SOCIETY. Sioux Falls. Three days: June 4th to 6th.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION. Los Angeles. Three days: May 6th to 8th.

SOUTHERN WISCONSIN DENTAL ASSOCIATION. Lancaster. Three days: May 21st to 23d.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA. Scranton. Three days: May 21st to 23d.

VERMONT STATE DENTAL SOCIETY. Burlington. Three days: May 15th to 17th.

JUNE.

AMERICAN MEDICAL ASSOCIATION—SECTION ON STOMATOLOGY. Atlantic City. Four days: June 4th to 7th.

COLORADO STATE DENTAL SOCIETY. Colorado Springs. Three days: June 20th to 22d.

FLORIDA STATE DENTAL SOCIETY. Atlantic Beach. Three days: June 6th to 8th.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: June 11th to 13th.

MASSACHUSETTS DENTAL SOCIETY. Boston. Three days: June 5th to 7th.

MICHIGAN STATE DENTAL ASSOCIATION. Saginaw. Two days: June 4th and 5th.

MISSOURI STATE DENTAL ASSOCIATION. Kansas City. Three days: June 4th to 6th.

NEW HAMPSHIRE DENTAL SOCIETY. Plymouth. Three days: June 25th to 27th.

SOUTH DAKOTA DENTAL SOCIETY. Sioux Falls. Three days: June 4th to 6th.

TEXAS STATE DENTAL ASSOCIATION. San Antonio. Three days: June 13th to 15th.

JULY.

NATIONAL ASSOCIATION OF DENTAL EXAMINERS. Minneapolis. Three days: July 26th to 29th.

NATIONAL ASSOCIATION OF DENTAL FACILITIES. Minneapolis. July 26th.

NATIONAL DENTAL ASSOCIATION. Minneapolis. Four days: July 30th to August 2d.

NEW JERSEY STATE DENTAL SOCIETY. Asbury Park. Three days: July 17th to 19th.

PENNSYLVANIA STATE DENTAL SOCIETY. Pittsburgh. Three days: July 9th to 11th.

TENNESSEE STATE DENTAL ASSOCIATION. Knoxville. Three days: July 9th to 11th.

Examiners' Meetings.

ALABAMA BOARD OF EXAMINERS. Birmingham. May 13th.

ARKANSAS BOARD OF EXAMINERS. Eureka Springs. May 27th and 28th.

CALIFORNIA BOARD OF EXAMINERS. Los Angeles, June 10th; San Francisco, June 17th.

CONNECTICUT DENTAL COMMISSIONERS. Hartford. June 13th to 15th.

DISTRICT OF COLUMBIA BOARD OF EXAMINERS. Washington. July 1st to 3d.

FLORIDA BOARD OF EXAMINERS. Jacksonville. June 3d.

ILLINOIS BOARD OF EXAMINERS. Chicago. June 3d.

INDIANA BOARD OF EXAMINERS. Indianapolis. June 11th to 13th.

IOWA BOARD OF EXAMINERS. Iowa City. June 6th to 11th.

KANSAS BOARD OF EXAMINERS. Topeka. May 22d to 25th.

KENTUCKY BOARD OF EXAMINERS. Louisville. June 4th.

MARYLAND BOARD OF EXAMINERS. Baltimore. May 22d and 23d.

MICHIGAN BOARD OF EXAMINERS. Ann Arbor. May 22d to 25th.

MINNESOTA BOARD OF EXAMINERS. Minneapolis. June 6th to 8th.

NEBRASKA BOARD OF EXAMINERS. Lincoln. May 29th to 31st.

NEW HAMPSHIRE BOARD OF REGISTRATION. Manchester. June 11th to 13th.

NORTH CAROLINA BOARD OF EXAMINERS. Morehead City. June 24th to 26th.

OHIO BOARD OF EXAMINERS. Columbus. June 25th to 27th.

SOUTH CAROLINA BOARD OF EXAMINERS. Anderson. June 28th.

SOUTH DAKOTA BOARD OF EXAMINERS. Sioux Falls. June 6th.

TENNESSEE BOARD OF EXAMINERS. Nashville. May 16th.

TEXAS BOARD OF EXAMINERS. San Antonio. June 10th.

VERMONT BOARD OF EXAMINERS. Montpelier. July 1st to 3d.

VIRGINIA BOARD OF EXAMINERS. Richmond. June 11th.

WEST VIRGINIA BOARD OF EXAMINERS. Wheeling. June 12th to 14th.

WISCONSIN BOARD OF EXAMINERS. Milwaukee. June 10th.

is also to receive its final settlement at Amsterdam.

Particular attention will be devoted to a matter which after a period of comparative quiet is again agitating the minds of dental teachers and practitioners, and which concerns the education which in future should be demanded of the dentist. The question whether the dentist should above all things be a full graduate in medicine, with a knowledge, more or less complete, of dentistry superadded, or should begin somewhat earlier to so shape his course as to best enable him to meet the demands which his profession and his patients make on him, is one which the F. D. I. has already pronounced upon in its session at Stockholm in August 1902. It cannot, however, be considered as having been definitely disposed of. It is, on the contrary, perhaps more acute at present than at any previous period in the history of our professional development.

The position of the F. D. I. having become more firmly established and its vote more authoritative, it is very desirable that its opinion should again be heard on this most important question, and every member should come prepared to give definite expression to his views.

Another point to be dealt with relates to the action of the committee of organization of the next international medical congress to be held in Budapest in 1909, in excluding from participation dentists who do not possess the medical degree. A consideration of the rights and duties of the F. D. I. in connection with the international dental congress to be held in Berlin in the same year will also take up some of the time.

These are a few of the matters which require special attention, and I sincerely hope that members will make every possible effort to be present. The steps taken toward the founding of an intellectual world-center at the Hague, if realized—and there seems to be every reason for trusting that such will be the case—will give an impulse to internationalism which will add greatly to the significance and importance of the F. D. I., and the hopes that it will be able to accomplish much in the interest of our profession and of humanity at large seem nearer fulfillment now than ever before.

W. D. MILLER, *President*.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

THE next meeting of the *Fédération Dentaire Internationale*, to be held at Amsterdam on August 8 and 9, 1907, promises to be one of exceptional interest, as a number of questions of great importance to the federation, as well as to the whole profession, must receive thorough consideration at that time.

Our experience has brought out a number of points in the rules and regulations which require to be cleared up. The question of a pamphlet containing specific directions for the care of the teeth, presented in a form adapted to widest circulation among the poor,

[JAMESTOWN EXPOSITION, NORFOLK, VA.,
1907.]

JAMESTOWN DENTAL CON- VENTION,

TO BE HELD AT

Norfolk, Va., Sept. 10-12, 1907.

Committee of Organisation.

BURTON LEE THORPE, St. Louis, Mo., *Chairman*.

H. WOOD CAMPBELL, Suffolk, Va., *Secretary*.

F. W. STIFF, Richmond, Va., *Treasurer*.

R. H. WALKER, Norfolk, Va.

THOS. P. HINMAN, Atlanta, Ga.

J. E. CHACE, Ocala, Fla.

CLARENCE J. GRIEVES, Baltimore, Md.

THE Jamestown Dental Convention will be held in a specially equipped building on the Exposition grounds which was built for the purpose of accommodating this convention. The building is equipped with an auditorium, committee rooms, and excellent facilities for conducting dental clinics and for holding exhibits, and all of these will be held in it. The entrance is outside of the grounds, but access to the grounds may be obtained through it. The building is wired with both direct and alternating current, equipped with running water, is well lighted, and contains all modern conveniences, thus making it an ideal convention hall. The exhibits are under the management of Dr. John W. Manning, Bank of Commerce bldg., Norfolk, Va. To him exhibitors should apply at once for space—price per foot and a plan of the hall will be sent upon request.

The clinics at the convention are under the supervision and direct control of Dr. C. J. Grievies, Park and Madison aves., Baltimore, Md. His assistants are Drs. Baskerville Bridgeforth, Richmond, Va., E. J. Tucker, Roxboro, N. C., Herbert Johnson, Macon, Ga., F. A. Bowles, Washington, D. C., and Joseph T. Meadors, Nashville, Tenn. The prospects are that the Jamestown clinic will be the largest and most complete dental clinic ever held. Assistant clinic chairmen have been appointed in each state in the Union and near countries, viz, Canada, Mexico, Cuba, and Hawaii. From these come reports of the enlistment of the best clinic talent in their respective states and countries.

Membership chairmen have been appointed in the various states and countries. Names of these and the clinic chairmen are given with the list of other officers in this issue of this journal. The membership committee is headed by Dr. F. W. Stiff, the general chairman, 600 East Grace st., Richmond, Va., who reports memberships rapidly coming in.

The hotel headquarters will be at the Inside Inn, where reasonable rates and excellent accommodations are assured. The Inside Inn generously offers numerous halls and committee rooms free of charge to the various college fraternities and alumni, who are invited to hold their meetings in these rooms. Later reports as to hotel accommodations and prices will appear in a subsequent issue.

The membership fee is five dollars, which will entitle members to receive a bound copy of the proceedings. A half-rate—\$2.50—is made to *bona fide* dental students upon certificates from the deans of their colleges, and when presented to the state chairman of the Membership Committee for indorsement and acceptance will entitle them to the rights and privileges of the convention.

The essayists are to be Prof. W. D. Miller of Berlin, Germany, "Demonstration of Preparations Relating to the Wasting (so-called Erosion) of the Teeth"; Dr. F. T. Van Woert of Brooklyn, N. Y., "Is the Cemented Filling the Filling of the Future?" Dr. Chas. L. Alexander of Charlotte, N. C., "Gold Inlays," and Dr. R. Ottolengui of New York city, "The Angle Method in Orthodontia."

Dr. E. P. Beadles was elected by the Committee on Organization in February to go to Europe and extend a cordial invitation to the dental societies and individual dentists to attend the convention.

The following officers were elected by the Committee of Organization at its recent meeting, February 23, 1907.

Officers.

Honorary President—Dr. J. Y. Crawford, Nashville, Tenn.

President—Dr. V. E. Turner, Raleigh, N. C.

First Vice-president—Dr. B. Holly Smith, Baltimore, Md.

Secretary-general—Dr. Geo. F. Keesee, Richmond, Va.

Treasurer—Dr. Mark F. Finley, Washington, D. C.

Vice-presidents—Chas. L. Alexander, Charlotte, N. C. R. R. Andrews, Cambridge, Mass. Waldo E. Boardman, Boston, Mass. Wm. M. Bebb, Los Angeles, Cal. G. V. Black, Chicago, Ill. Edwin C. Blaisdell, Portsmouth, N. H. F. A. Blanchard, Marksville, La. George W. Boynton, Washington, D. C. Truman W. Brophy, Chicago, Ill. Geo. V. I. Brown, Milwaukee, Wis. H. J. Burkhardt, Batavia, N. Y. AMERICAN MEDICAL ASSOCIATION—SECTION ON STOMATOLOGY.

FOLLOWING is the program of the American Medical Association—Section on Stomatology, for its annual meeting at Atlantic City, N. J. June 4 to 7, 1907:

1. Chairman's Address. M. I. Schamberg, New York city.
2. "The Necessity of a Medical Education for Dentists."
 - (a) "From the Standpoint of the Lay Public." M. L. Rhein, New York city, H. C. Registrar, Philadelphia, and James McManus, Hartford, Conn.
 - (b) "From the Standpoint of the Physician." V. A. Latham, Chicago.
3. "The Common Ground of Dentistry and Medicine." F. L. Fossum, New York city.
4. "The Mutual Development Dependence of the Upper Air-Tract, the Jaws, the Teeth, and the Face; and their Economic Importance to the Human Race." W. Sohler Bryant, New York city.
5. "The Relation of Upper Respiratory Obstruction to Oral Deformity. Simultaneous Treatment by Expansion of the Dental Arch." Francis A. Faught, Philadelphia.
6. "Speech Results of Cleft Palate Operations." George V. I. Brown, Milwaukee.
7. "Technique of Lip and Palate Operations." Thomas Fillebrown, Boston.
8. "False Statements Concerning Causes of Pathological Conditions." S. B. Luckie, Chester, Pa.
9. "Acid Auto-intoxication; the Principal Cause of Erosion and Abrasion." Eugene S. Talbot, Chicago.
10. "Some Results from Orthodontia on the Deciduous Teeth." E. A. Bogue, New York city.
11. "Osteomyelitis of the Maxilla." Samuel L. Goldsmith, New York city.
12. "A Case of Epidermoid Carcinoma of the Inferior Maxilla." W. H. Potter, Boston.
13. "Pregnancy: a Factor in the Etiology of Dental Diseases." James E. Power, Providence, R. I.
14. "The Dentist in the United States Navy." Richard Grady, Annapolis.

15. "The X Ray an Aid to the Stomatologist." R. G. Richter, Milwaukee.
16. "Radiography in Oral Surgery, with Demonstrations of a Focus Finder and Ray Localizer." G. E. Pfahler, Philadelphia.

M. I. SCHAMBERG, *Chairman*.
EUGENE S. TALBOT, *Sec'y*.

NATIONAL DENTAL ASSOCIATION.

THE eleventh annual session of this association will be held in Minneapolis, July 30 and 31, and August 1 and 2, 1907, when a full program of essays, demonstrations, and clinics will be presented. Reduced rates on all railways and at hotels will be secured. The largest meeting in the history of the association is confidently expected. Full program in July journals.

The following are the officers of the sections and chairmen of clinics and local arrangements:

SECTION I:

Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

D. O. M. LE CRON (chairman), Missouri Trust bldg., St. Louis, Mo.

W. G. MASON (vice-chairman), Tampa, Fla.

E. P. DAMERON (secretary), 58 De Menil bldg., St. Louis, Mo.

SECTION II:

Operative Dentistry, Nomenclature, Literature, Dental Education, and Allied Subjects.

WM. CRENSHAW (chairman), 621 Prudential bldg., Atlanta, Ga.

JOHN I. HART (vice-chairman), 118 W. Fifty-sixth st., New York city.

J. J. SARRAZIN (secretary), Godchaux bldg., New Orleans, La.

SECTION III:

Oral Surgery, Anatomy, Physiology, Histology, Pathology, Etiology, Hygiene, Prophylaxis, Materia Medica, and Allied Subjects.

WM. CARR (chairman), 35 W. Forty-sixth st., New York city.

W. H. G. LOGAN (vice-chairman), 785 Winthrop ave., Chicago, Ill.

M. L. RHEIN (secretary), 38 E. Sixty-first st., New York city.

CLINICS.

E. K. WEDELSTAEDT (chairman), 204 New York Life bldg., St. Paul, Minn.

SECTION ON INLAYS.

WALTER N. MURRAY (chairman), 601 Medical blk., Minneapolis, Minn.

LOCAL COMMITTEE OF ARRANGEMENTS.

F. B. KREMER (chairman), Masonic Temple, Minneapolis, Minn.

Delegates received only from state societies, but a cordial invitation is extended to all reputable practitioners to attend the meeting.

C. S. BUTLER, *Sec'y*,
267 Elmwood ave., Buffalo, N. Y.

A. H. PECK, *President*,
92 State st., Chicago, Ill.

Clinic Section.

THERE is every indication that there will be a large clinic held in Minneapolis on July 31st and August 1st. Many men have signified their intention to be present and take part in either the operative work, or else give some kind of a table clinic. If I am to judge from what has been written to me, we shall have a most interesting meeting, so far as the clinic is concerned.

In the past there has been some criticism regarding the clinic room being so far away from headquarters. In no sense of the word is the Clinic Committee to be blamed for this condition of affairs. It must take what is offered, or else not have clinical demonstrations. Now, this year there is every assurance that this condition will be materially changed. Dr. F. B. Kremer, the chairman of the Local Committee of Arrangements, is a man of much experience in dental society work—therefore he is the very man for the place. He knows what is desired, and beyond question he will secure a hall for the clinic room in close proximity to headquarters. This year, at least, those contemplating being with us need not worry about this special part of the meeting, for Dr. Kremer is a man who does not neglect anything.

From reports which are constantly being received there is every reason to believe that we shall hold a most successful clinic.

The following gentlemen are acting as district and state chairmen:

DISTRICT AND STATE CHAIRMEN.

New England States. Dr. G. E. Savage, Worcester, Mass.

New York. Dr. F. L. Fossum, N. Y.

New Jersey, Delaware, and District of Columbia. Dr. M. F. Finley, Washington, D. C.

Maryland. Dr. C. M. Gingrich, Baltimore, Md.

Virginia and West Virginia. Dr. F. W. Stiff, Richmond, Va.

North and South Carolina and Georgia. Dr. H. H. Johnson, Macon, Ga.

Florida, Alabama, and Mississippi. Dr. A. T. Reeves, Selma, Ala.

Tennessee and Kentucky. Dr. W. M. Slack, Memphis, Tenn.

Pennsylvania. Dr. H. E. Friesell, Pittsburgh.

Ohio. Dr. H. C. Brown, Columbus.

Indiana. Dr. C. D. Lucas, Indianapolis.

Illinois. Dr. F. W. Gethro, Chicago.

Wisconsin. Dr. S. H. Chase, Madison.

Ontario.

Manitoba. Dr. K. C. Campbell, Winnipeg.

It is not an easy matter to arrange the program, and I shall be grateful to all the chairmen for their list of clinicians. The earlier the list is sent the better.

E. K. WEDELSTAEDT, *Ch'man Clinic Section*,
N. Y. Life bldg., St. Paul, Minn.

NATIONAL ASSOCIATION OF
DENTAL EXAMINERS.

THE National Association of Dental Examiners will hold their twenty-fifth annual meeting in Minneapolis, Minn., beginning Friday, July 26th, and continuing through the 27th and 29th. A large attendance of delegates is earnestly requested.

Accommodations have been secured in the leading hotel of Minneapolis—The West Hotel. Rates will be as follows: Rooms without bath, \$1.00 per day for each occupant; with bath, \$2.00 per day for one person, and \$1.50 per day for each additional person in room. The hotel is run on the European plan. Any room in the hotel is capable of accommodating two people. All the rooms have telephone connection, and hot and cold water. Railroad rates will be given later.

The Committee on Colleges, Joint Confer-

ence Committee, Tabulation of Examining Boards' Reports, and the Committee for Promoting a System of Credits and Uniformity of Examinations will all give exceedingly interesting reports, valuable to all the members of the association.

CHAS. A. MEEKER, *Sec'y-Treasurer*,
29 Fulton st., Newark, N. J.

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

THE annual meeting of the National Association of Dental Faculties will be held in Minneapolis, Minn., commencing at 2 P.M., Friday, July 26, 1907.

The Executive Committee will meet at 10 A.M. the same day. The West Hotel has been selected as headquarters and place of meeting. Hotel rates as published in the notices of the meeting of the National Association of Dental Examiners will prevail.

H. B. TILESTON, *Ch'man Ex. Committee*,
B. HOLLY SMITH, *Sec'y Ex. Committee*,
1007 Madison ave., Baltimore, Md.

FIRST FRENCH CONGRESS OF STOMATOLOGY.

A CONGRESS of stomatology, styled the First French Congress of Stomatology, will take place in Paris from August 1 to 5, 1907.

The Committee of Organization is as follows: Drs. Galippe and Redier, honorary presidents; Dr. Cruet, president; Drs. Claude Martin of Lyons, and J. Ferrier, vice-presidents; Dr. Chompret, general secretary; Dr. Gires, treasurer.

The Congress will be open to all French and foreign doctors of medicine who are interested in dental and oral science. Subscriptions and communications should be addressed to

DR. CHOMPRET, *General Sec'y*,
182 rue de Rivoli, Paris.

ST. LOUIS DENTAL COLLEGE.

ALUMNI CLINIC.

THE Alumni Association of the St. Louis Dental College (formerly Marion-Sims) wish to announce that their annual clinic will be

held at the college building, Grand ave. and Caroline st., on Tuesday and Wednesday, May 7 and 8, 1907.

All ethical members of the profession are cordially invited to come and enjoy the festival of good things being prepared, and every member of the alumni is especially requested to show his allegiance to the association by his presence.

JOHN BERNARD O'BRIEN,
W. L. O'NEILL,
Committee on Publicity.

UNIVERSITY OF PENNSYLVANIA.

DENTAL ALUMNI SOCIETY.

THE twenty-seventh annual meeting of the Dental Alumni Society of the University of Pennsylvania will be held in Philadelphia, June 15, 17, and 18, 1907. This will be an extremely interesting meeting, the number of clinics and social features being unusually large.

PROGRAM.

Saturday, June 15th—3 P.M. Aquatic sports in the gymnasium pool: races, water-polo, and fancy swimming.

4 P.M. "Varsity" baseball team vs. graduates, Franklin Field; admission free.

6 P.M. Alumni supper, Weightman Hall gymnasium.

7.45 P.M. Annual business meeting, General Alumni Society, Weightman Hall.

8 P.M. Reception to wives of alumni, Houston Hall and adjoining campus.

8.30 P.M. Reunion of classes in the dormitory triangle and lighting of the Bonfire. Special quarters for alumni of the dental department.

Monday, June 17th—10 A.M. Clinics and demonstrations, Dental Hall, both morning and afternoon.

7 P.M. The twenty-seventh anniversary banquet, Dental Alumni Society at the Bartram.

Tuesday, June 18th—10 A.M. Annual business meeting, Dental Hall.

2 P.M. University grounds and buildings open for inspection.

There will be special rates on all railroads. For further information, address,

VICTOR COCHRAN, *Sec'y*,
1628 N. Seventeenth st., Phila.

PHILADELPHIA DENTAL COLLEGE.

ALUMNI SOCIETY MEETING.

THE Alumni Society of the Philadelphia Dental College will celebrate Alumni Day, Friday, May 31, 1907, in the college buildings at Eighteenth and Buttonwood sts., Philadelphia, Pa. The dental profession is cordially invited to be present.

At 10 A.M. a series of clinics will be given under the auspices of the clinic committee, composed of Dr. C. R. Jefferis, chairman, Drs. Max Greenbaum and W. G. Chase.

At 2.30 P.M. the business meeting will be held in the amphitheater of the college, which will be presided over by Dr. Wm. T. Wyckoff. After Dr. Wyckoff has delivered the presidential address, Dr. L. A. O'Brian of New York city will read the annual paper. The discussion of this paper will then ensue. The faculty will present some very interesting dental topics, and make college announcements.

The alumni banquet will occur Friday evening, May 31st. An announcement of the time, place, and cost per cover will be made later on. The banquet committee, consisting of Dr. W. G. Chase, chairman, Drs. M. F. Quinn, and Harvey Iredell, have full charge, and applications should be made to them for covers. The faculty, trustees, students, graduating class, and alumni will be warmly welcomed at the banquet.

An unusual feature of Alumni Day is the fact that it is the last to be held under the old *régime*. This year the Philadelphia Dental College enters into a federation with Temple College. Dr. Russell H. Conwell will be president of the new board of trustees. There will also be a new secretary and treasurer, but Dr. Leo Greenbaum remains dean, and the faculty continue the same.

ALPHONSO IRWIN, *Sec'y*.

WASHINGTON UNIVERSITY DENTAL DEPARTMENT.

MEETING OF ALUMNI.

A MEETING of the Alumni Association of Washington University Dental Department (Missouri Dental College) will be held May 20 and 21, 1907, at the college building, 2645 Locust st., St. Louis, Mo.

A number of prominent essayists and clini-

cians have been secured, and an interesting and instructive program will be presented. Adequate space has been secured for the various manufacturers' exhibits; this will be a noteworthy feature of the meeting. All ethical practitioners are invited.

A. J. PROSSER, *Chairman*,
F. W. HORSTMANN,
CHAS. HERBERT.

UNIVERSITY OF PENNSYLVANIA, DENTAL DEPARTMENT.

CLASS OF 1902.

THE fifth annual reunion of the class of 1902, Dental Department of the University of Pennsylvania, will be held on Alumni Day, Saturday, June 15, 1907. All are earnestly requested to make an effort to come back to their alma mater on that day.

J. ARTHUR STANDEN, *Sec'y*,
1220 Locust st., Philadelphia. Pa.

DETROIT DENTAL COLLEGE.

ALUMNI CLINIC AND BANQUET.

THE sixteenth annual commencement exercises of the Department of Dental Surgery of the Detroit College of Medicine will be celebrated on May 30, 1907, with an elaborate clinical program and banquet. All reputable practitioners are invited.

P. J. O'REILLY,
Detroit, Mich.

OREGON STATE DENTAL ASSOCIATION.

At the last meeting of the Executive Committee of the Oregon State Dental Association, it was decided to hold the annual meeting in Portland, Ore., May 9, 10, and 11, 1907.

JEAN CLINE, *Sec'y-Treasurer*,
Portland, Ore.

GEORGIA STATE DENTAL SOCIETY.

THE next annual meeting of the Georgia State Dental Society will be held in Atlanta, May 7, 8, 9, and 10, 1907. All ethical practitioners are cordially invited to attend.

D. H. MCNEILL, *Cor. Sec'y*,
Athens, Ga.

KENTUCKY STATE DENTAL ASSOCIATION.

THE next annual meeting of the Kentucky State Dental Association will convene at Louisville, Ky., May 20, 21, and 22, 1907. We anticipate a most interesting and profitable meeting. A cordial invitation is extended to the profession.

W. M. RANDALL, *Sec'y*,
Louisville, Ky.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

THE tenth annual session of the Southern California Dental Association will be held in Los Angeles, May 6, 7, and 8, 1907, at the same time that the Imperial Council of Mystic Shrine meets here, and all members of the dental profession contemplating visiting southern California at that time will confer a favor upon the association by notifying

CHAS. M. BENBROOK, *Sec'y*,
455 S. Broadway, Los Angeles, Cal.

NEBRASKA STATE DENTAL SOCIETY.

THE thirty-first annual meeting of the Nebraska State Dental Society will be held in Lincoln, May 21, 22, and 23, 1907, at the Lincoln Dental College. The Lindell Hotel will be headquarters. All reputable members of the profession are invited to attend.

M. E. VANCE, *Sec'y*,
Lincoln, Nebr.

VERMONT STATE DENTAL SOCIETY.

THE thirty-first annual meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 15, 16, and 17, 1907.

The society has in the past held most successful meetings, and we have every reason to expect that this will surpass any previous one, as a very interesting program has been prepared by the committee, and will be mailed in due time. Vermont has the largest per cent. of membership in its state society of any state in New England, and we hope to see every dentist in the state who is eligible a member.

THOMAS MOUND, *Sec'y*,
Rutland, Vt.

NEW YORK STATE DENTAL SOCIETY.

THE thirty-ninth annual meeting of the New York State Dental Society will be held at Hotel Ten Eyck, Albany, May 10 and 11, 1907, convening promptly at 10 o'clock on the morning of the first day, at which time the president desires to see every member present. A program of reports and essays of unusual interest will be presented, and on Saturday afternoon a large number of special chair and table clinics will be given. A cordial invitation is extended to all reputable practitioners to attend the sessions.

PROGRAM.

Dr. W. A. White, President's Address.

Dr. A. H. Peck, Chicago, "The Value of Association."

Dr. Clarence J. Grieves, Baltimore, "The Soldered Porcelain Facing Checked: Causes and Remedies." Illustrated.

Dr. Eugene Talbot, Chicago, "Acid Auto-intoxication and Systemic Diseases the Cause of Erosion and Abrasion."

Dr. L. C. F. Hugo, Washington, "Preparing Dental Papers."

Dr. G. V. I. Brown, Milwaukee, "Oral Surgical Lessons." Illustrated.

Dr. Chas. McManus, Hartford, "Pierre Fauchard." Illustrated.

Dr. Nelson T. Shields, New York city, "Treatment and Filling of Root-canals."

Dr. I. C. Curtis, Fulton, N. Y., "Fifty Years of Dental Science, with its Fads and Foibles."

Dr. S. L. Goldsmith, New York city, Report of the Correspondent.

Dr. E. Howard Babcock, Brooklyn, Report of the Committee on Practice.

Dr. Emanuel Muntz, Buffalo, Report of the Committee on Scientific Research: "Saliva Sulfocyanate Test."

There will be an interesting exhibit of dental appliances and supplies by the leading dealers in the country. For any information regarding exhibits, address Dr. J. L. Appleton, 89 Columbia ave., Albany, N. Y.

A railway rate of a fare and one-third, on the certificate plan, for those attending the meeting will be secured. Tickets at full fare for the going journey may be purchased within three days previous to and during the first day of the meeting. Be sure, when pur-

chasing ticket, to request a certificate. On arrival at the meeting, present the certificate, with twenty-five cents, to the secretary, Dr. C. S. Butler.

Tickets good returning not later than May 15th.

W. A. WHITE, *President*.

CHAS. S. BUTLER, *Sec'y*,
Buffalo, N. Y.

SIXTH DISTRICT (N. Y.) DENTAL SOCIETY.

THE thirty-ninth annual meeting of the Sixth District Dental Society of the state of New York will be held at the Hotel Bennett, Binghamton, N. Y., Thursday and Friday, May 2 and 3, 1907. Cross off these dates now.

FRED FORD, *Sec'y*,
Cazenovia, N. Y.

IOWA STATE DENTAL SOCIETY.

THE forty-fifth annual meeting of the Iowa State Dental Society will be held at Cedar Rapids, Iowa, May 7, 8, and 9, 1907. A good program is being arranged for. A cordial invitation is extended to the profession.

C. L. TOPLIFF, *Sec'y*,
Decorah, Ia.

EASTERN INDIANA DENTAL ASSOCIATION.

THE Eastern Indiana Dental Association will meet in Anderson, Ind., May 14 and 15, 1907. Good clinics, good papers. Everybody invited. Everybody who comes is a member.

C. W. ORLAND,
Anderson, Ind.

ODONTOTECHNIQUE SOCIETY OF NEW JERSEY.

THE regular monthly meeting of the Odontotechnique Society of New Jersey will be held at Achtel-Stetter's, Newark, N. J., on Saturday evening, May 4, 1907. The paper of the evening will be read by D. A. Webb, M.D., of Scranton, Pa., president of the Scranton Clinical and Pathological Society—subject, "Diseases of the Jaws: Malignant Growths, Fractures, etc."

H. J. GIBBINS,
Newark, N. J.

ILLINOIS STATE DENTAL SOCIETY.

THE forty-third annual meeting of the Illinois State Dental Society will be held at Quincy, on Tuesday, Wednesday, Thursday, and Friday, May 14, 15, 16, and 17, 1907.

ARTHUR D. BLACK, *Sec'y*,
31 Washington st., Chicago.

SOUTHERN WISCONSIN DENTAL ASSOCIATION.

THE thirteenth annual meeting of the Southern Wisconsin Dental Association will be held at Lancaster, Wis., May 21, 22, and 23, 1907. All reputable practitioners are cordially invited.

C. W. COLLVER, *Sec'y*,
Clinton, Wis.

ARKANSAS STATE DENTAL ASSOCIATION.

THE Arkansas State Dental Association will hold its annual meeting at Eureka Springs, Ark., May 29, 30, and 31, 1907.

HENRY P. HOPKINS, *Sec'y-Treas.*,
Argenta, Ark.

LAKE ERIE DENTAL ASSOCIATION.

THE forty-fourth annual meeting of the Lake Erie Dental Association will be held at Hotel Rider, Cambridge Springs, Pa., on May 21, 22, and 23, 1907.

Upon our program this year are men of exceptional merit, and we are pleased to invite all reputable dentists and their friends to this beautiful place for convention purposes.

V. H. MCALPIN, *Sec'y*,
Warren, Pa.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

THE Susquehanna Dental Association of Pennsylvania will convene in Scranton, at Saint Luke's Parish House, for its forty-fourth annual meeting, on Tuesday, Wednesday, and Thursday, May 21, 22, and 23, 1907.

A large number of papers and clinics has been secured from many prominent members of the profession in New York state and Philadelphia, as well as from our own members

The largest manufacturers' exhibit ever held by this society has also been secured. Non-members desiring a copy of the program are requested to communicate with the secretary.

An afternoon and evening will be devoted to an outing at Moosic Lake, a near-by mountain resort, with an altitude of 2000 feet.

A cordial invitation is extended to all ethical practitioners.

EDMOND J. DONNEGAN, *Recording Sec'y*,
22 Amsden bldg., Scranton, Pa.

ALABAMA DENTAL ASSOCIATION.

THE next annual meeting of the Alabama Dental Association will be held in Birmingham, Ala., May 14 to 17, 1907. Reduced rates on all railroads. All ethical dentists are invited to attend.

F. A. JOHNSTON, *Sec'y*, Sheffield, Ala.

MISSISSIPPI DENTAL ASSOCIATION.

THE fourteenth annual meeting of the Mississippi Dental Association will convene in the county court-house in Meridian, May 28, 29, and 30, 1907. All ethical practitioners of this and other states are cordially invited to attend. Reduced railroad rates and reduced hotel accommodations will be secured.

For full particulars, address

E. DOUGLAS HOOD, *Sec'y*, Tupelo, Miss.

TEXAS STATE DENTAL ASSOCIATION.

THE Texas State Dental Association will hold its meeting in the city of San Antonio, June 13, 14, and 15, 1907.

G. W. STAPLES, *Sec'y*, Dallas, Tex.

INDIANA STATE DENTAL ASSOCIATION.

THE forty-ninth annual meeting of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, June 11, 12, and 13, 1907. The Executive Committee has arranged an unusually interesting program for this meeting. A cordial invitation is extended to the profession to be present.

CARL D. LUCAS, *Sec'y*,
Indianapolis, Ind.

MICHIGAN STATE DENTAL ASSOCIATION.

CHANGE OF DATE OF MEETING.

THE annual meeting of the Michigan State Dental Association will be held in Saginaw, June 4 and 5, 1907. All ethical practitioners are cordially invited to attend.

L. N. HOGARTH, *Sec'y*, Detroit, Mich.

NEW HAMPSHIRE DENTAL SOCIETY.

THE annual meeting of the New Hampshire Dental Society will be held at Plymouth, N. H., June 25, 26, and 27, 1907, beginning on the evening of the 25th. All members of the profession are cordially invited to be present.

FRED F. FISHER, *Sec'y*, Manchester, N. H.

SOUTH DAKOTA DENTAL SOCIETY.

CHANGE OF DATE OF MEETING.

THE twenty-fifth annual meeting of the South Dakota Dental Society will be held at Sioux Falls, June 4, 5, and 6, 1907.

A most interesting program has been arranged, and we want to see the largest attendance the society has ever had. A larger membership is desired, and every eligible dentist in the state should become a member. Dentists of southeastern Minnesota and northwestern Iowa are specially invited.

FERDINAND BROWN, *Sec'y*, Sioux Falls.

MASSACHUSETTS DENTAL SOCIETY.

THE forty-third annual meeting of the Massachusetts Dental Society will be held in the Mechanic Association bldg., Huntington ave., Boston, Mass., June 5, 6, and 7, 1907.

An excellent program has been arranged by the Executive Committee. It will consist of essays, reports of special committees, clinics, and a large exhibit of dental and medical supplies. Special committees will report on the following interesting subjects: Tuberculosis and other preventable diseases, dental education, dental supplies, dental medicine, dental research, and dental hospitals. Gentlemen practicing dentistry in Massachusetts are invited to join the society.

CHARLES W. RODGERS, *Sec'y*,
165 Howard st., Dorchester, Mass.

FLORIDA STATE DENTAL SOCIETY.

THE twenty-fourth annual meeting of the Florida State Dental Society will be held in the ballroom of the Hotel Continental, at Atlantic Beach, Thursday, June 6, 1907, continuing in session three days. All ethical practitioners of dentistry are cordially invited to attend.

CARROLL H. FRINK, *Cor. Sec'y*,
Fernandina, Fla.

MISSOURI STATE DENTAL ASSOCIATION.

THE next annual meeting of the Missouri State Dental Association will convene in Kansas City, Mo., June 4, 5, and 6, 1907. A most interesting and profitable meeting is anticipated. All ethical members of the profession are cordially invited to attend.

E. P. DAMERON, *Cor. Sec'y*,
St. Louis, Mo.

COLORADO STATE DENTAL SOCIETY.

THE annual meeting of the Colorado State Dental Society will be held at Colorado Springs, June 20, 21, and 22, 1907. A good program is being arranged and a profitable meeting is assured. An invitation to attend is extended to all ethical dentists, and special efforts will be put forth to make it pleasant for visitors from other states.

The undersigned would be pleased to hear from any who may plan to attend the meeting.

I. C. BROWNIE, *Ch'm Exec. Com.*,
404 California bldg., Denver, Colo.

NEW JERSEY STATE DENTAL SOCIETY.

THE thirty-seventh annual meeting of the New Jersey State Dental Society will be held in the Auditorium at Asbury Park, N. J., commencing 10 A.M. July 17th and continuing through the 18th and 19th. The headquarters will be at the Hotel Columbia, at the rates of \$3.50 and \$4.00 per day, and all reservations must be made before July 1st.

Prominent dentists have signified their intention of reading papers, and the clinics will all be of a new and novel nature. Clinic

committee in charge of Charles H. Dilt, Trenton, N. J.; exhibit committee in charge of Walter Woolsey, Elizabeth, N. J. Programs will be out June 15th.

Last year over eight hundred dentists registered in attendance. The Auditorium where the meeting is held is the largest and best adapted building on the Jersey coast. Cut off the week of July 15th, and be with us.

CHARLES A. MEEKER, *Sec'y*,
29 Fulton st., Newark, N. J.

PENNSYLVANIA STATE DENTAL SOCIETY.

THE Pennsylvania State Dental Society will hold its thirty-ninth annual meeting on July 9, 10, and 11, 1907, at the Schenley Hotel, Pittsburg, Pa.

LUTHER M. WEAVER, *Sec'y*,
Philadelphia, Pa.

TENNESSEE STATE DENTAL ASSOCIATION.

THE fortieth annual meeting of the Tennessee State Dental Association will be held at Knoxville, Tenn., July 9, 10, and 11, 1907. All are cordially invited. Reduced railroad rates will be secured, and a successful meeting is anticipated.

R. J. MCGAVOCK, *Sec'y*,
Columbia, Tenn.

NEBRASKA BOARD OF EXAMINERS.

THE next meeting of the Nebraska Board of Dental Examiners will be held at the State-house, in Lincoln, Nebr., May 29, 30, and 31, 1907. All applicants for examination must have their applications in the hands of the secretary five days before this date.

For further information address.

C. F. LADD, *Sec'y*,
1241 O. st., Lincoln, Nebr.

MICHIGAN BOARD OF EXAMINERS.

THE Michigan Board of Examiners in Dentistry will hold their next meeting for the examination of candidates at the dental department of the University of Michigan, at Ann Arbor, May 22, 23, 24, and 25, 1907.

E. A. HONEY, *Sec'y*,
Kalamazoo, Mich.

ARKANSAS BOARD OF EXAMINERS.

THE Arkansas State Board of Dental Examiners will hold examinations at Eureka Springs, Ark., May 27 and 28, 1907.

A. T. McMILLIN, *Sec'y*,
Little Rock, Ark.

MARYLAND BOARD OF EXAMINERS.

THE regular semi-annual meeting of the Maryland State Board of Dental Examiners for the examination of candidates for certificates will be held May 22 and 23, 1907, at the Baltimore College of Dental Surgery, Baltimore, at 9 A.M. Application blanks and full information will be furnished by

F. F. DREW, *Sec'y*,
701 N. Howard st., Baltimore, Md.

TENNESSEE BOARD OF EXAMINERS.

EXAMINATION UNDER AMENDED DENTAL LAW.

THE Tennessee Dental Law has been recently so amended as to require all applicants for registration to be graduates of reputable dental colleges, and they must also pass a written examination by the State Board, and give a practical demonstration of proficiency in operative and prosthetic dentistry. Examination fee, \$10.00. The board will hold its annual meeting at Nashville, May 16, 1907.

With the other important amendments made at the same time, the Tennessee dental law is now on a par with the dental laws of other states.

F. A. SHOTWELL, *Sec'y*,
Rogersville, Tenn.

ALABAMA BOARD OF EXAMINERS.

THE Board of Dental Examiners for the State of Alabama will meet in Birmingham, Ala., on the Monday before the second Tuesday in May 1907. In addition to the regular written examination, each applicant must fill at least two teeth—approximal cavities—one with gold, the other with alloy, work to be done under the immediate supervision of the board. The board will determine or pass on suitable selections of cavities, and will try to furnish subjects, but, it failing to do so, applicants for license must find or bring

their own subjects, also instruments and materials.

Each applicant must take or have taken an impression of his own mouth. Make a plaster cast of the same, cut from the cast the six anterior teeth, and make a bridge for same with porcelain facings. Cast can be made and facings fitted before the examination, but the backings must be put on and the facings arranged, also invested and soldered, under the supervision of the board, hard solder being required.

THOS. P. WHITBY, *Sec'y*,
Selma, Ala.

KANSAS BOARD OF EXAM- INERS.

THE Kansas State Board of Dental Examiners will hold their next meeting for examination in Topeka, May 22, 23, 24, and 25, 1907, at the Copeland Hotel annex. The examination fee will be \$25.00, with an additional fee of \$5.00 for a license. Examination will not be necessary for a graduate of a reputable dental college. The fee for registering a diploma is \$25.00.

Address all communications to

F. O. HETRICK, *Sec'y*, Ottawa, Kans.

VIRGINIA BOARD OF EXAMINERS.

THE next meeting of the Virginia State Board of Dental Examiners will be held at the Medical College of Virginia, Richmond, Va., beginning at 9 A.M. Tuesday, June 11, 1907.

R. H. WALKER, *Sec'y*, Norfolk, Va.

ILLINOIS BOARD OF EX- AMINERS.

THE next regular meeting of the Illinois State Board of Dental Examiners for the examination of applicants for a license to practice dentistry in the state of Illinois will be held in Chicago, at the Northwestern University Dental School, southeast corner of Lake and Dearborn sts., beginning Monday, June 3, 1907, at 9 A.M.

Applicants must be in possession of the following requirements in order to be eligible to take the examination: (1) Any person who has been engaged in the actual, legal, and lawful practice of dentistry or dental surgery in some other state or country for five

consecutive years just prior to application; or (2) is a graduate of and has a diploma from the faculty of a reputable dental college, school, or dental department of a reputable university, or (3) is a graduate of and has a diploma from the faculty of a reputable medical college or medical department of a reputable university, and possesses the necessary qualifications prescribed by the board.

Candidates will be furnished with proper blanks and such other information as is necessary, on application to the secretary. All applications must be filed with the secretary five days prior to the date of examination. The examination fee is twenty (\$20) dollars, with the additional fee of five (\$5) dollars for a license.

Address all communications to

J. G. REID, *Sec'y*,
1204 Trude bldg., Chicago, Ill.

OHIO BOARD OF EXAMINERS.

THE regular semi-annual meeting of the Board of Dental Examiners of the State of Ohio will be held in Columbus, June 25, 26, and 27, 1907. Only graduates are eligible to examination. Application, accompanied by fee (\$20.00), should be filed with the secretary by June 15th. For further information address

H. C. BROWN, *Sec'y*,
185 E. State st., Columbus, Ohio.

INDIANA BOARD OF EXAMINERS.

THE next regular meeting of the Indiana State Board of Dental Examiners will be held in the Capitol at Indianapolis, June 11, 12, and 13, 1907. Applications must be in the hands of the secretary at least five days before the above date. Address

F. R. HENSHAW, *Sec'y*,
Middletown, Indiana.

NORTH CAROLINA BOARD OF EXAMINERS.

THE next meeting of the North Carolina Board of Dental Examiners will be held at Morehead City, N. C., June 24, 25, and 26, 1907. Applicants must register on or before 9 A.M. June 24th.

For further information address

R. H. JONES, *Sec'y*, Winston-Salem, N. C.

WISCONSIN BOARD OF EXAMINERS.

THE next meeting of the Wisconsin Board of Dental Examiners for examination of candidates for license to practice dentistry in Wisconsin will be held Monday, June 10, 1907, at the Wisconsin College of Physicians and Surgeons, Milwaukee, Wis.

Application must be made to the secretary fifteen days before examination. The candidate must be a graduate of a reputable dental college, or have been engaged in the reputable practice of dentistry for four consecutive years, or has been an apprentice to a reputable dentist for five years.

For further particulars apply to

J. J. WRIGHT, *Sec'y*,
1218 Wells bldg., Milwaukee, Wis.

FLORIDA BOARD OF EXAMINERS.

THE Florida State Board of Dental Examiners will meet June 3, 1907, at 10 o'clock, in Jacksonville, Fla., for the purpose of examining applicants for license to practice in this state.

Applicants must furnish instruments in practical work, and in addition to the written examination will be required to put in one gold filling, one alloy filling, and to solder and finish one four-tooth bridge under supervision of the board. Bring bridge ready for investing. Only graduates of reputable dental schools are admitted to examination.

W. G. MASON, *Sec'y*,
Tampa, Fla.

SOUTH DAKOTA BOARD OF EXAMINERS.

THE next examination of the South Dakota State Board of Dental Examiners will be held at Sioux Falls, S. D., beginning at three o'clock June 6, 1907, and continuing three days. All candidates are required to bring operating instruments, including dental engine, and such other appliances and materials as are necessary to do crown and bridge work. All applications, together with the fee, ten dollars, must positively be in the hands of the secretary by June 3d, and no application will be considered thereafter.

G. W. COLLINS, *Sec'y*,
Vermillion, S. D.

TEXAS BOARD OF EXAMINERS.

THE Texas State Board of Dental Examiners will hold their next regular meeting at San Antonio, Texas, June 10, 1907, at 10 A.M. For further information address

C. C. WEAVER, *Sec'y*,
Hillsboro, Texas.

CALIFORNIA BOARD OF EXAMINERS.

THE next examination of the California Board of Dental Examiners will be held in Los Angeles beginning June 10, and in San Francisco beginning June 17, 1907.

C. A. HERRICK, *Sec'y*,
Jackson, Cal.

NEW HAMPSHIRE BOARD OF REGISTRATION.

THE next meeting of the New Hampshire Board of Registration in Dentistry for examination of applicants for registration will be held in Manchester, N. H., June 11 to 13, 1907.

A. J. SAWYER, *Sec'y*,
Manchester, N. H.

WEST VIRGINIA BOARD OF EXAMINERS.

THE West Virginia State Board of Dental Examiners will hold their next meeting for the examination of candidates at Wheeling, W. Va., June 12, 13, and 14, 1907. For further information address

H. M. VAN VOORHIS, *Sec'y*,
Morgantown, W. Va.

KENTUCKY BOARD OF EXAMINERS.

THE Kentucky State Board of Dental Examiners will meet for the examination of applicants at Louisville, Ky., June 4, 1907, at The Masonic, commencing at 9 A.M.

Each applicant for examination shall be required to deposit with the secretary of the board his or her recent photograph, with signature on the reverse side, both of which shall be certified to by the dean of his or her graduating college, or other parties accept-

able to the board. Applicants must be graduates of reputable dental colleges.

Every applicant shall be required to treat two or more teeth affected with pyorrhea; to insert two gold fillings; two amalgam fillings; impression, bite, and articulating teeth of upper and lower denture; one bridge on model, consisting of one shell and one Richmond crown and two porcelain-face dummies; one gold or porcelain inlay or Logan crown, one practical case diagnosis; all to be done before the board. A general average of 75 per cent. is required. Applicants will be graded upon a basis of 60 per cent. on practical work and 40 per cent. on theory.

Applicants must come prepared with instruments, engine and material, excepting bellows, blowpipe, lathe, stones, and polishing cones, to do the above-mentioned work.

The board would advise the use of gold in the above bridge, as it would cost very little more than German silver after disposing of it.

Application for examination must be made upon blanks furnished by the board, and must be accompanied by a fee of \$20.00.

J. RICHARD WALLACE, *President*,
The Masonic, Louisville, Ky.

IOWA BOARD OF EXAMINERS.

THE Iowa State Board of Dental Examiners will hold its next meeting for examination at Iowa City, June 6, 7, 8, 10, and 11, 1907. Applicant must hold a diploma from a college on the accredited list of the National Association of Dental Examiners, and must state where he attended first, second, and third year of college. Address

E. D. BROWER, *Sec'y*, Le Mars, Iowa.

MINNESOTA BOARD OF EXAMINERS.

THE Minnesota State Board of Dental Examiners will hold a special meeting at the dental building of the state university, in Minneapolis, June 6, 7, and 8, 1907. All applications must be in the hands of the secretary by 10 o'clock June 6th, as examinations will begin at 10.30 o'clock sharp. All blanks, paper, and patients supplied by the board. Operating instruments, etc., must be brought by the applicant. Any further information will be given by addressing

GEO. S. TODD, *Sec'y*, Lake City, Minn.

SOUTH CAROLINA BOARD OF EXAMINERS.

THE South Carolina Board of Dental Examiners will meet in annual session at Anderson, S. C., on June 28, 1907, to examine applicants for license. For further information address

BROOKS RUTLEDGE, *Sec'y*,
Florence, S. C.

CONNECTICUT DENTAL COMMISSIONERS.

THE Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford on Thursday, Friday, and Saturday, June 13, 14, and 15, 1907, to examine applicants for license to practice dentistry, and for the transaction of any other business proper to come before said meeting.

Applicants should apply to the recorder for proper blanks and rules for conducting the examination. Application blanks must be filled in and sworn to, and with fee, filed with the recorder on or before June 6, 1907. By order of Commission.

GILBERT M. GRISWOLD, *Recorder*,
783 Main st., Hartford, Conn.

DISTRICT OF COLUMBIA BOARD OF EXAMINERS.

THE semi-annual examination of the Board of Dental Examiners of the District of Columbia will take place July 1, 2, and 3, 1907. All applications must be accompanied with a fee of ten dollars, and should be filed not later than June 22d with

WM. B. DALY, *Sec'y*,
1340 New York ave. N. W.,
Washington, D. C.

VERMONT BOARD OF EXAMINERS.

A MEETING of the Vermont State Board of Dental Examiners for the examination of candidates will be held at the State-house, Montpelier, Vt., Monday, Tuesday, and Wednesday, July 1, 2, and 3, 1907, commencing at 2 o'clock of July 1st. All applications, together with the fee, \$25.00, must be in the hands of the secretary not later than June 23d. Application blanks and further information may be obtained from

GEO. F. CHENEY, *Sec'y*,
St. Johnsbury, Vt.

ORIGINAL COMMUNICATIONS.

THE TEETH IN RELATION TO EAR AND THROAT DISEASES.

By C. P. GRAYSON, M.D., Philadelphia, Pa.

(Read before the Southern Dental Society of New Jersey, April 17, 1907.)

AT the very beginning of my paper I regret that my conscience compels me to make a rather mortifying confession, which is that I have much reason for believing that the members of my profession, and even of my own specialty, are not nearly so generally alive to the intimate relationship existing between the diseases of the nose, throat, and ear, and those of the teeth, as are the members of yours. It is, for instance, not at all an infrequent occurrence in my work to have patients sent to me by some of the Philadelphia dentists who realize that in order to obtain a successful result from some prosthetic or other measure that they contemplate, an essential preliminary will be the removal of a mass of adenoids from the patient's naso-pharynx, or perhaps of a pair of enlarged faucial tonsils or a marked deflection of the septum that may

be seriously interfering with nasal respiration, and consequently with the normal development of the dental arch.

And in the same way it has been brought to my notice that many of you dental surgeons are quick to recognize that certain of the nutritional disturbances affecting the teeth are dependent upon chronic digestive impairment that is attributable to some catarrhal affection of the nose and throat. And yet how often do I meet with cases of chronic lacunar tonsillitis, or of persistent pharyngeal and laryngeal catarrhal inflammations, that have resisted treatment for months simply because the throat specialist has entirely overlooked or has failed to sufficiently appreciate the etiological influence of a depraved dental condition, and has neglected to call upon you for advice and assistance! It is scarcely to be supposed

that any rhino-laryngologist fails to recognize that the nose represents, both anatomically and physiologically, the threshold of the respiratory tract, but is there any less reason for his clear perception of the fact that it is the teeth that bear precisely the same relation to the digestive tract? Probably no one would dispute the assertion that it is impossible to have a perfectly healthy throat and lower air-passages in association with an unhealthy nose; and yet, I repeat, there seem to be a surprisingly large number of physicians who see no incompatibility between diseased teeth and a normal digestive tract below them.

Of course it is my privilege to speak only of those portions of the digestive tract with which my special work makes me the most familiar—the mouth, the fauces, and the pharynx; but in my writings and lectures for almost the past score of years I have never neglected the opportunity to emphasize the importance of gastro-intestinal sanitation as an aid to the successful treatment of nose, throat, and ear diseases. There is never a class that graduates from the Medical Department of the University of Pennsylvania without having been repeatedly told that the very first thing to examine when a patient presents himself for the relief of some nasal or throat trouble is the condition of the teeth.

PHYSIOLOGICAL ANALOGY BETWEEN THE NOSE AND THE TEETH.

The physiological analogy between the nose and the teeth is a most striking one. It is the nose alone that by filtering, warming, and moistening the air, prepares it for its subsequent reception by the bronchial tubes and the pulmonary cells; and it is just as exclusively to the teeth that the processes of digestion and assimilation look for the thorough and essential preparation of the food materials that they are subsequently to work upon. It will surely be perfectly apparent that the analogy between these two structures extends likewise into the domain of pathology, for if they are dis-

eased to any material extent the ultimate implication of the lower portions of the tracts of which they represent the beginnings will be inevitable. If they are diseased the respiratory and nutritive streams are both poisoned at their respective sources, and all the remote and later effects of this poisoning will prove irremediable until these primary foci of disease are restored to health.

So much for considerations of a general nature, and now, with a closeness of their relation thoroughly appreciated, it will not be difficult to compile a list of those diseases of the nose, throat, and ear that are etiologically dependent upon dental disease.

PATHOGENIC CONNECTION BETWEEN THE TEETH AND THE MIDDLE EAR.

To begin with the ear, the frequency of acute median otitis in association with the dentition of childhood is a well-known occurrence, and the conveyance of the irritation from the gums to the middle ear is easily explained by the intercommunication of the nerve supply of the two structures. May I recall to your memories the communication of the greater superficial petrosal nerve with the tympanic plexus, and by means of the Vidian nerve with Meckel's ganglion, which is associated with the superior maxillary nerve, from which the supply of the upper teeth is derived. The small superficial petrosal nerve is also in connection with the tympanic plexus and joins the otic ganglion, and in this way communicates with the inferior maxillary nerve and its inferior dental branch to the lower teeth. The pathogenic connection between the teeth and the middle ear is by no means demonstrated only in children; in adults I have failed a number of times to make much impression upon chronic purulent inflammations of the tympanum until I had secured through the co-operation of the dentist the removal of a persistent reflex irritation of dental origin.

In passing from the ear to the throat, I would like to stop for a moment or two

at the nose, and exchange ideas with you concerning the inflammations of the largest and most frequently affected of its accessory cavities—the maxillary sinus. Here we are on common ground, for the diagnosis and treatment of disease in this cavity are as much a part of your work as of that of the rhinologist. To be perfectly frank, I must confess that with reference to the comparative frequency of etiologic activity on the part of the teeth and of intranasal disease in the production of the antral inflammations, I have been during the past twelve or fifteen years more or less of a shuttlecock. My first opinion was that the teeth were the more often responsible for the antral involvement, but during several added years of experience I accumulated sufficient reason, I thought, for changing my views, and gradually came to believe that it was to infection or to simple extension of inflammation from the nasal fossæ that the larger number of antral inflammations were due; and then, once more, after an unusually long and almost unbroken series of cases that were of unmistakably dental origin, I drifted back to my first opinion. Now, however, with a little further shifting of my ground, I think that I am finally anchored, and I should say that if we exclude the many cases of maxillary sinusitis that are secondary to the infective rhinitis of influenza and grippe, the majority of all the others are traceable to the teeth. Possibly you may tell me a few things tonight that may compel me to modify even this opinion, but I think it is a pretty conservative one

now, and that it will not need much alteration.

THROAT DISEASES AND NEGLECT OF THE TEETH.

And now, to descend to the faucial region and the throat, I am perfectly confident that many obstinate cases of chronic lacunar tonsillitis have arisen from and have continued because of neglect of the teeth, and I am equally sure that in the production of a large number of acute infective inflammations of the tonsils, pyorrhea alveolaris and dental caries have played an active part. Am I wrong in thinking that there could scarcely be a more fertile and nutritious soil for the breeding of pathogenic organisms than that found in the cavity of a carious tooth? And when such cavities become over-populated, it is but a short journey to the crypts of the tonsils, which soon become the sites of new and thriving bacterial colonies.

Finally, I think that I am justified in believing that even chronic *laryngeal* catarrhs may be maintained, if not originated, by such diseases of the teeth and gums as I have mentioned. There is no occasion and there would be no excuse for my wearying you with the details of a number of cases in evidence of this, but I need only to say in support of my belief that in spite of the re-establishment of the health of the nose and nasopharynx, these laryngeal catarrhs will all prove refractory until the teeth and the alveolar tissues are put in equally good condition.

LOCAL ANESTHESIA IN DENTAL OPERATIONS.

By VAL MACDONALD, L.R.C.S.Ed., D.D.S., Univ. Pa., Melbourne, Australia.

IN this nerve-racking age of ours all seem to be living the strenuous life, with the safety-valve screwed down, and the determination to reach the goal of success or burst in the attempt. The

result is, in greater or lesser degree according to the length and intensity of the struggle, a case of nerves! nerves! nerves!

No one is perhaps more faced with the

difficulties in dealing with the overwrought, highly strung nervous individual than the modern dentist. From earliest times there has existed an almost instinctive dread of the dental chair and its associations. In those early times, with clumsy instruments, with lack of knowledge of asepsis, and without anesthetics, the operator being also without any scientific knowledge of his craft, small wonder that such a dread existed!

But time has rolled on, and with it the modern dentist has been evolved, with a more or less exact knowledge of his work begotten of scientific training and the assistance of beautiful instruments, anesthetics general and local, and asepsis. The forceps has replaced the barbarous locking key, and the dental engine has reached perfection, and is no longer the "infernal machine" of our forefathers. With all ordinary dental operations it is no longer necessary to associate extreme pain; and the old-time dread is gradually becoming dust-covered in the recesses of ancient memories.

PAIN IN CAVITY PREPARATION.

In cavity preparations, for example, it is seldom that extreme pain need be caused if the operator have the necessary knowledge of the anatomy of the tooth. One of the greatest causes of pain is, I feel sure, the use of blunt burs, also too prolonged use in one spot, causing overheating with its resultant pain. In many cases it is sufficient to use a warm solution of sodium bicarbonate to allay any hypersensitiveness of dentin, especially where the cavity has been left for a few days with a cotton dressing in it. If this plan fails, or in addition to it, the usual methods, *i.e.* applying carbolic or Robinson's remedy, etc., after thoroughly drying the cavity, may be employed, and are usually found to be efficacious. These and sharp burs are the simple remedies sufficient for ordinary cases in the average patient. But the nervous patient comes along, afraid of anything and everything, and pain, however slight, is "acute." Also, in the average

patient, a really hypersensitive cavity is met with. How must we deal with such cases?

Remedies are at hand; so also is the danger of their abuse—as ably pointed out in the editorial in the December issue of the *Cosmos*, wherein it is said that "The resort to anesthetics, or other artificial means for escaping the primal curse, is too often a device which 'makes cowards of us all,' by destroying the powers of both moral and physical resistance to the ordinary stress of life. There is a danger in this tendency to continually 'sugar-coat' disagreeable human sensations, because it will in time destroy the power of human endurance."

ON THE USE OF COCAIN INJECTION.

Also, the same editorial, in criticizing the method of obtunding sensitive dentin advocated by Professor Touchard and others, that of cocaine injection, takes exception as to the risk of introducing "a poisonous drug into the circulation, with its attendant risks of septic infection;" and continues, "and while from a scientific point of view the method described by Touchard is interesting, and while it may have a useful place in isolated and extreme cases, we consider its promulgation as a method to be generally employed as one fraught with large possibilities of danger. We regard it as wrong on moral grounds, because it panders to that weakness of nervous resistance which is the basis of inebriety, hysteria, low moral tone, and loss of vigor, which in its protean manifestations is so insidiously undermining the social fabric."

The dangers so pointed out of the indiscriminate use of this method of anesthesia are very real, and cannot be too frequently brought before the dental profession or public. With many distinctly nervous and hysterical cases it requires but one or two visits, with firm sympathy and care, to reduce such patients to a normal level, so to speak. It will generally be found that such individuals have suffered severely—and all too unnecessarily—at other hands, and

have good reason for the fear which it is the first duty of the operator to dissipate.

When "pain within reasonable limits" is looked upon as a "moral tonic," it at once calls for a definition of "a reasonable limit."

"PAIN WITHIN REASONABLE LIMITS."

When chloroform and ether were first introduced, strong objection was raised in many quarters against any attempt "to annul a pain that God had intended should be borne." More especially was this heard in connection with midwifery and the use of chloroform. Many women can go through even the ordeal of childbearing without a thought of any anesthetic. Modern dress has no doubt done much to render that ordeal more difficult in many cases, but even to the savage such anesthesia would often come as a blessing, and few would now be found to refuse its aid.

The "reasonable limit" must depend upon two factors—(1) The individual. (2) The operator.

Many people have a dread of a general anesthetic, and it seems unnecessary to subject such persons to one if some safe local anesthetic will answer—provided anything at all is necessary. Take a case in which the extraction of one or more teeth is called for. Are we to use a local or a general anesthetic? We must first consider which class is the safer, and again make further choice from whichever class, local or general, is chosen. So, again, occasion may arise in which we must consider whether a cavity, which is extremely sensitive, should be prepared with or without other than the ordinary means of obtunding sensitive dentin. Is the pain or the anesthetic employed likely to do most injury to the individual?

I have known of dentists who, to obtain a slight peripheral anesthesia, allowed the patient to inhale from time to time a small quantity of ether or chloroform—a practice sufficiently dangerous to condemn absolutely in the mere mention.

In 1905, when in Edinburgh, I was impressed by the major operations so frequently performed with the aid of cocaine and adrenalin chlorid, or with eucain and adrenalin chlorid, though the first combination was much preferred. I was also struck with the growing use of cocaine solutions for purposes of extraction. Seeing the use of cocaine so successful in general surgery, I could not see why it should not be safely used by the dentist, and determined myself to try it, first for cases of extraction. In these cases I worked with a 1 per cent. solution of cocaine hydrochlorid, and the results so pleased me that one day, in cutting an extremely sensitive cavity in which I had tried all the usual remedies without good result, I injected 15 minims of the 1 per cent. solution around the tooth. The result was a slightly lessened sensitivity of the dentin, but not greatly so. I left a dressing in the tooth, and next day used the combination of cocaine and adrenalin chlorid, and the effect was complete anesthesia of the hypersensitive dentin.

Since that time I have used the combination for all extractions in which I have used local anesthesia, also in the few cases in which I have found it necessary for purposes of excavation. Although I have used it in some 150 cases of extraction I have never had the slightest sign of sloughing or ill effect. My method has been as follows:

METHOD OF USING COCAINE-ADRENALIN SOLUTION.

Preparation of solution. To a 1 per cent. solution of cocaine hydrochlorid I add an equal quantity of a 1:10,000 solution of adrenalin chlorid in normal saline solution. This gives me therefore a solution containing $\frac{1}{2}$ per cent. solution of cocaine with 1:20,000 of adrenalin. This strength is sufficient to give perfect anesthesia when from 10 to 15 minims are injected around the tooth, either for extraction or excavation; and working with a solution of known strength is essential in order to keep within safe limits. The gum is now well swabbed

with an antiseptic solution over the area to be injected on both sides of the tooth. The injection is now made slowly, the blanching of the gum giving a rough idea of the extent injected. I do not find it necessary to make a very deep injection, and never inject with the point of the needle on the periosteum, as I believe that may be one source of trouble met with; for I can conceive that if injected into the resisting periosteal or bone tissue, the congestion which always follows the use of cocain might cause thrombosis (through strangulation) in the small vessels of that area just as does arsenic when applied to the dental pulp. With this precaution and the use of a thoroughly sterilized syringe and fresh solution, there can be but little danger of cellulitis, sloughing, or necrosis. Although Drs. Cryer and Perry have reported cases of necrosis and ascending degeneration of nerve trunks after the use of cocain injections, by other operators, they could not give the requisite information as to conditions under which the injections were made as regards health and condition of patient, preparation of mouth, sterilization of syringe and fresh solution or strength of the solution used. I am of opinion that in those cases due regard to these points by the operators did not obtain.

The use of the adrenalin enables a considerably less and weaker quantity of cocain to be used; for by its constricting action on the vessels of the part it delays the too rapid absorption of the cocain and so gives it a longer time in contact with the parts it is sought to anesthetize.

The resulting anesthesia is no doubt in part due to the direct action of the drugs and in part a pressure anesthesia. The increased pressure caused by the volume of the solution restricted by the tissues assists in forcing the drugs into the tissue adjacent and so helps the anesthetic action.

Already some men use cocain and adrenalin in the preparation of all cavities simply for the sake of a "painless" reputation and without a due regard to the merits of the case. Such abuse is to be utterly condemned as unworthy of

the profession. It is the abuse and not the judicious use of any mode of procedure that is open to criticism.

Even if the patient object to a general anesthetic for an extraction, it is for the operator to judge whether he should or should not operate under one. The feelings of the patient must on no account be allowed to override the better judgment of the operator.

If the operator incline to cocain rather than to a general anesthetic, he must first be sure that the risk is less in "introducing a poisonous drug into the circulation" by this method, than by inhalation as with a general anesthetic. Cocain may be considered contra-indicated in cases of known peculiar susceptibility to its toxic effects, in pregnancy, in hysterical subjects—in all those, indeed, to whom slight shock is likely to bring untoward effects. In such cases nitrous oxid is considerably safer, especially in the hands of the novice. The likelihood of the cocain habit being induced is, I believe, remote where so small a quantity and so weak a solution as I have described is used.

The flush and rapid pulse caused by the adrenalin after the first few minims are injected rapidly pass away and need not cause alarm.

PRECAUTIONS.

If used for excavating sensitive dentin, I would emphasize the fact that it is seldom necessary. Where it will be found useful is in painful cervical cavities. In cavities which are in close proximity to the pulp, or where the pulp has been much irritated, the use of cocain and adrenalin is, I believe, distinctly contra-indicated, for the after-congestion may cause further pain and even death of the pulp. In any case where used for excavating I think it advisable on completion of the filling to use a counter-irritant on the gum to lessen the risk of after-congestion of the pulp. I also desire to emphasize the fact that only a $\frac{1}{2}$ per cent. solution of cocain is necessary, and that whatever strength is employed not more than $\frac{1}{4}$ grain of co-

cain should be injected. Thorough asepsis is a most necessary adjunct to success in this as in any other operation, and I fear that the syringe including the needle, is too frequently a sad offender in this respect. The solutions used should be freshly prepared, and the habit of filling the syringe from the bottle cannot be too strongly condemned. Rather pour out the quantity required into a sterilized porcelain dish, or watch-glass, and fill the syringe from that.

In conclusion I would say that while I agree in great part with the sentiments expressed in the December editorial referred to, I do not altogether do so.

There is surely a moral courage requisite to bow to defeat and to cry "Enough!" as well as to continue a hope-

less struggle at the certain cost of wrecking the organism. So, in considering the degree of pain to be inflicted and endured, we must weigh it in the scale with the chosen anesthetic, and judge as to whether the pain or the anesthetic will do the least harm; and in the majority of cases where it is necessary to so consider, I believe the verdict will be for the anesthetic. The Spartan youth who hid the stolen wolf beneath his toga and suffered the agony of disembowelment rather than utter the cry that would proclaim him a thief showed a rare courage. But that same Spartan youth, of such proved grit, by casting out the wolf, acknowledging his lapse, and devoting the vital energy thus saved to better things had surely done his country an infinitely greater service!

ORAL HYGIENE IN PUBLIC SCHOOLS AND INSTITUTIONS: WHAT ARE WE GOING TO DO ABOUT IT?

By **RICHARD GRADY, M.D., D.D.S.,** *Annapolis, Md.*

(Read at the union meeting of the Maryland State Dental Association and the District of Columbia Dental Society, Washington, June 9, 1906.)

A DENTAL practitioner's insistence upon the value of the teeth and the importance of their preservation is quite often regarded by the laity as a professional exaggeration which need not be taken too seriously. What is said in dental journals is to a great extent ineffective, because of their failure to reach the people. Hence the progress of public sentiment respecting the teeth has been necessarily slow.

It is seldom that we have an opportunity to declare ourselves in public, or that anything said by us on the subject of dentistry, or the teeth, commands general attention; yet when Professor Osler, in an address in England last fall, urged that the mouth and its contained organs be kept in a clean and hygienic condition, together with routine inspec-

tion of the teeth of school children, and educating the public along dental lines so that better nutrition and consequently better health may be secured, these sentiments which have been uttered by us for years were published in many medical journals and newspapers, accompanied at times with favorable editorial comment.

SOME PREVIOUS WORK ON THIS SUBJECT.

The subject chosen for me by the committee of arrangements is not a new theme in my hands, but is one on which my pen and voice have often been busy. In a reprint of my graduation thesis in 1879, I appended some rules for preserving the teeth, with the comment that there is scarcely a subject of personal

character so sadly neglected, or so little understood by the public, as the care of the teeth. Later being made chairman of the Maryland State Dental Association committee on oral hygiene in public schools, I made a study of the question under three heads—What do we want? Why do we want it? What is the best way of getting it?—in a paper read before the American Medical Association entitled "Co-operation of the Public Schools in Teaching Good Teeth, Good Health." Still later (in 1900) I offered a resolution in the National Dental Association, asking for the appointment of a special committee to consider the expediency of inaugurating steps looking to the co-operation of the public schools in teaching oral hygiene, and upon the appointment of such a committee, was made its chairman—an office which I endeavored to fill with conscientious fidelity up to the time it was entrusted to another last year, having been in communication with dentists at home and abroad who have made uniform examinations of the teeth of children from six to fifteen years of age. The results of this systematic propaganda are recorded in the Transactions of the National Dental Association from 1900 to 1903 inclusive; in the Transactions of the International Dental Congress (1904), under the title "Benefits of Mastication and Insalivation," and elsewhere in circulars and dental journals. I have endeavored to keep the subject alive and get it a hearing whenever in my power. It is encouraging to know that good ideas have extraordinary vitality.

Can I find anything new to say on this question, which is assuming greater importance in the minds of conscientious and progressive practitioners, whose sole and unselfish purpose is to promote hygienic conditions in the mouth, and who recognize that there is a responsibility resting on the profession which should command serious consideration? Can I place old thoughts in such a new light that they may, perchance, strike a responsive chord, and by so doing stimulate other thoughts to our advantage? I speak from the varied experience of

twenty-seven years as a visiting dentist to schools and institutions, and an opportunity such as few, if any, dentists have had of noting the teeth of young people from six to twenty-four years of age.

AS OTHERS SEE US.

We stand in the limelight of the twentieth century, and have earned for ourselves an honorable place; but judged by a distinguished educator quoted by Dr. Potter of Boston, "The dental profession seems most interested in repairing broken-down structures, and too little in preventing such conditions"; or in the words of Governor Hastings of Pennsylvania, "Dentists live inside a tooth until they become cranks."

In these pictures we "see ourselves as others see us," and the words are somewhat confirmed by Dr. Crawford of Nashville, who says, "We get together and brag about being the greatest profession in the world. Let us get up and stop bragging, and do something! Dental caries is ravaging this country; this is attributable very largely to our lethargy. Let us get up and do something; then the people will stop calling us 'tooth-carpenters,' and will pay some attention to what we say. We should act as a solid phalanx, and when a man sees a right thing he should indorse it, whether it comes from the east, west, north, or south. Let us stand up for what is right."

Dentistry as an organized profession is younger than either law or medicine. The public is consequently not so familiar with it and the benefits it confers, but gains its knowledge largely from grossly misleading advertisements of the dental parlors. Many dentists do not take the trouble to teach their patients how essential sound teeth are to their well-being—the relation of clean teeth to good health—that cleanliness does away largely with the tendency to decay. A campaign of education should be carried on in every dental office, and by every dental organization. The responsibility of every dentist is great; the responsibility of every dental and medical school,

and of every dental association and dental examining board, is greater. We are all responsible to the future. "That one should be ignorant who has capacity for knowledge—this I call tragedy," says Carlyle.

Civil service reform is so wide in its scope that we find it has special interest for every class of the people. The fact that it requires a physical, as well as a mental and moral examination of candidates for office, commends it to all who are especially interested in the physical improvement of the race. The hygienic value of the dental feature came out unexpectedly at a meeting of the National Civil Service Reform League, which I attended recently in this city. One of the speakers told of a mechanic in the "East side" of New York, who, having achieved popularity in his neighborhood, aspired to become a "ward leader." A proper preliminary step, he decided, was to be enrolled on the police force. He attended night school to fit himself for the necessary examination, which he passed with credit; but he was rejected by the physical examiners on the ground that he was the victim of dyspepsia. His teeth had been neglected in his youth, mastication was imperfect, and dyspepsia was the result. The examiners held very wisely that dyspepsia tends to irritability; and that a man suffering with this disease would lack the judicial calm which is so characteristic of the New York policemen. The man was an altruist in spite of his dyspepsia. He went to his friends and supporters and told his experience, and the result was a boom in tooth-brushes throughout the entire ward.

A MATTER OF TIME.

If we expect immediate results from education, we shall be disappointed. It is safe to estimate that it takes a period of from thirty to fifty years—let us say the time of one generation—to secure the popular approval of matters of minor importance; while to establish greater principles, a longer period is usually involved. If we take a more extended

view of the subject, and point the public in the right direction, the condition is not hopeless. It is "up to us," in the language of the day, to follow the high ideas of Dr. S. G. Perry of New York, who says, "The social as well as the professional status of the dentist of today is determined by the dentist himself. If he be an educated gentleman, all high places will be open to him." As to the future he says, "I venture to predict that we shall acquire a keener sense of our responsibilities, be more alert in the prevention of diseases of the teeth, and more careful to instruct our patients in their proper care. We shall be more alive to the importance of prophylaxis. It will eventually assume first place in our practice."

DR. EVANS' RECEPTION BY NAPOLEON III.

Dr. Evans in his "Memoirs" just published, says of Napoleon III, "He found the dental art to be of great use to him, and accordingly had an excellent opinion of dentists in general, and saw no reason why they should not be as proud of their specialty as the practitioners of any branch of medicine or surgery"; and adds "I was richly repaid in many ways, but more especially by the direct support and encouragement he gave me in the practice of my art and the social consideration he accorded to me, and through me to my profession. At a ball to which Mrs. Evans and myself had been invited, we overheard a conversation. 'Who is that woman?' said one lady to another; 'she is so delicate and lady-like—she looks like an American!' 'Yes, she is,' was the reply; 'and only think, she is the wife of a dentist! How dreadful!' A few minutes later the emperor approached us and shook hands with us both.

"As an American citizen I had never thought it would be necessary for me to feel ashamed of myself socially, or that I was to be deprived of the privileges and civilities usually conceded to practitioners of the liberal arts and professions. The emperor quickly saw how I felt about the position I was to hold in his

immediate *entourage*; and, since he was not disposed to recognize distinctions of any kind among men, except such as were determined by intelligence, personal accomplishments, or special abilities, I was very soon admitted to the Elysée officially on a footing of equality with doctors of medicine, surgeons, university professors, and men of science in general. When the court was established, I received my appointment of 'surgeon dentist,' and in the same form and on the same terms as the other doctors and surgeons. My court dress was the gold-embroidered special uniform worn by every member of the medical staff. We all received the same compensation. Once having a standing at the imperial court, the way was opened for my reception at other courts. I am sure that the consideration which had been shown to me by nearly all the royal families of Europe has been of very great service to me personally; and I am equally sure, but still more pleased to believe, that my profession has been benefited and honored also."

DR. OLIVER ON THE STATUS OF THE
"CONTRACT DENTAL SURGEON."

All of which—especially the "footing of equality with doctors of medicine," "same compensation," and "gold-embroidered special uniform worn by every member of the medical staff"—is in striking contrast to the picture presented by Dr. Oliver, U. S. Army Dental Surgeon at West Point, in his paper at the last meeting of the National Dental Association. He said "The present status of the contract dental surgeon is continually a source of humiliation and degradation to all, and to those more sensitive men, who have occupied social positions at their homes equal to the best in their several communities, it is of course more keenly felt. In the matter of uniform we are especially unfortunate. . . . It is absolutely impossible to tell a dental surgeon from an enlisted man of the Hospital Corps at a distance of ten feet. . . . It seems a great injustice to educated professional men, who have spent

years in acquiring a technical and scientific knowledge of their specialty, and who have qualified before a competent examining board before entering the service, to be so meanly uniformed. . . . What is urgently required is . . . that there may be some future held out to the successful and efficient dental surgeon . . . where he may enjoy the social distinction of a post without reserve and without feelings of humility, and can appear like the rest of the officers at the various functions, formal and informal, and who at various military ceremonies can feel and act as an officer and a gentleman."

With the development of the mechanical aspect of dentistry, which has resulted in such a degree of perfection in methods, appliances, and technique of dental practice as to leave little room for further improvement of a radical character, has come, as a result of experience, a fuller knowledge of its limitations as a remedial agency. It may be pleasing to some to learn of the admiration of the English writer who tells in the *Fortnightly Review* that "hundreds of thousands of dentists are forever filling and scraping and pulling American teeth," and who says, "The American dentist is the greatest in the world. Not only does he produce an exact copy of nature, but his is the only instance known to science where human ingenuity excels nature's—his teeth do not ache"; or the words of Oliver Wendell Holmes, "The dental profession has taken from old age its most unwelcome feature, and lengthened enjoyable human life far beyond the limit of years when the toothless and purblind patriarch might well exclaim, 'I have no pleasure in them!'"

I believe we have come to a point in our history where we should take another step, and a very important one, where in the words of Edward Everett Hale, "We must serve the world, not like the handcraftsman, for a stipend accurately representing the work done, but as those who deal with infinite values and confer benefits as freely and nobly as does nature."

ORAL HYGIENE.

Not repeating what I have previously written, except for reference, I want to plead in this twenty-minute paper—and not tax your patience longer—for oral hygiene—which includes dental examination and attention—in public schools and institutions for the children of the state, such as schools for orphans and the blind, hospitals, reformatories, and fresh-air societies; and to ask the members of this union meeting to say what they are going to do about it, especially in providing leaflets to be used in school physiologies.

Personally, I have been earnestly striving for years to make instruction in oral hygiene an essential part of public school education, which would be an agency to bring such knowledge into the home life of the people, thus identifying it with the health of the household. I have made routine examinations of the teeth and recorded them on charts—which correct errors in those previously published—thus confirming statements that a systematic examination of the teeth of children at home and abroad reveals the fact that from ninety-two to ninety-five per cent. have defective teeth, so that there is no longer need of further statistics of this kind; have called attention to the mischievous teaching respecting the teeth in school physiologies; have issued pamphlets to school officers as a means of spreading information respecting the need of teaching oral hygiene in public schools, believing that school officers and other friends of education will be most willing to receive it. The parent, the teacher, and the newspaper editor, it is hoped, will be enlisted in the cause. The scheme is essentially an educative one, and thousands of dentists, scattered throughout the country, who command confidence and respect, can be counted on to assist in the work, which would be entirely altruistic and free from what might be called professional selfishness. Now what have you done, personally?

In this city (Washington) Dr. H. C. Thompson informs me, relative to school

hygiene: "We undertook that work on plans of extensive scale, when, by reason of the superintendent, it was stopped. He wanted us to do all the work and give the results to him, thereby giving him credit for it all, and allowing the profession to remain in the background. Of course everything stopped right there, and still stands *status quo*."

In Baltimore, a committee of which I was chairman—with Dr. B. Holly Smith, the president of the National Dental Association, who appointed the committee on oral hygiene in public schools, Dr. G. Marshall Smith, who seconded the resolution in the National Dental Association calling for the appointment of the committee, and Dr. Wm. A. Mills, on whose motion the Maryland State Dental Association appointed a standing committee on oral hygiene—appeared before members of the school board by invitation fully four years ago, and requested permission to examine the mouths and teeth of pupils from six to fifteen years of age in four white schools and one colored school in different sections of that city, and to give brief talks to the students of the city college and high schools on the care of the teeth.

We argued that few persons realize what an important part the teeth play in the preservation of health, presenting statistics, and saying that we would inculcate in children the virtue of mouth-cleanliness, and teach them hygienic habits which would stand them in good stead their life long; that no difficulty ought to be encountered on the part of school officers in introducing lessons on the care of the mouth and teeth. After the meeting I was told by a member of the board that our arguments made no impression. As Dr. Hayden said about his idea of a national convention of dentists in 1817: "The pear was not ripe."

OUR MOTIVES SOMETIMES DISTRUSTED.

Why we failed at that time has been partly explained: (1) In the statement that one of our professional brothers—who couldn't conceive how a man who is really competent would devote

much time to work that did not directly promise a money return—had represented to a rabbi, a member of the school board, that our motive was mercenary and that we wanted the pupils for patients. (2) In the conversion of the *ex-officio* member of our committee to these unfair and prejudiced sentiments of another member of the school board: "The method would make the public schools unpopular; the movement would not be tolerated by the Johns Hopkins University and Woman's College; hence why should the poor man, because of his necessity, be subjected to anything he would resist were it in his power? By what authority does the school board order such an examination other than that it would affect the health of the neighborhood pupils by infection?" (3) The indifference of members of the association, fifty of whom were invited to appear before the school board and only five of whom responded. In this connection I want to record my recognition of the broad-minded president of the Johns Hopkins University, Dr. Ira Remsen, then a member of the school board, who said to me, "I am in favor of it on your statement without any argument."

Our experience is not singular, but is very much like that of the committee in San Francisco of which Dr. Frank I. Platt tells. He is particularly interested in the examination and care of the teeth of the children in school, though he does not know what course can be taken to bring about that much desired condition of affairs. He said that he was appointed on a committee to interview the board of education in San Francisco to see what could be done there, and he does not believe that he was ever treated more shabbily in his life, although he started out with honest intentions. On reviewing the work done in Europe and in some of our eastern cities and states, the committee did not seem to be at all impressed with the importance of the matter. When Dr. Platt referred to the fact that several years before the board had appointed an oculist to examine the eyes of the children in schools, it was insinuated that pecuniary profit had a

part in the motives of the profession concerned. These bodies must be impressed with the importance of this work. Back of it all there must be a change in education; dentists must be better educated. With men and women who realize the importance of this specialty, and who are enthusiastic, there will be an impulse that will not be put down. Dr. Platt stated that he has spent considerable time in working along this line, and is utterly disheartened to find how few men or women are really enthusiastic. Most of them are working for bread and butter. It is hard to arouse any enthusiasm, and I think the fault lies in the foundation—in the teaching. It is of vital importance to the coming generation of people in this and every civilized country that mouths be taken care of. If the authorities could be so impressed with the importance of this matter that they could not pass it over with a slur, then something might be accomplished. It might be a good plan for some of the profession to be elected mayors of cities.

DENTISTS MAY BECOME SCHOOL COMMISSIONERS.

If dentists can't become mayors, as advised by Dr. Platt, they may become school commissioners like Dr. Stiff in Richmond, where "absolutely no objection was raised and consent was at once granted." He writes, "I have found absolutely no opposition on the part of teacher, scholar, or parent."

CONCLUDING REMARKS.

I need hardly say to you, in conclusion, that our responsibility is the central thought of this paper; that the limited instruction given in our public schools on the care of the teeth is not sufficient; that the mere filling of a tooth—as typifying dental clinics—or the reading of papers to and at each other is not fully living up to our obligations.

We are called upon for more than this, and our code of ethics demands that we shall "educate the public mind so that

it will properly appreciate the beneficent efforts of our profession." It is time that those who would call themselves "professional" should truly realize the needs of their fellow men, for the health of the individual, for the comfort of the family, for the welfare of the state.

Dental education of the public, es-

pecially the children, given by and under the auspices of our district society and state association, will do more to stop quackery than legislation—a thing that ought to be done and should be done. "It is a holy thing," in the words of Lord Beaconsfield, "to see a nation saved by its youth."

FREE DENTAL SERVICE IN THE PUBLIC SCHOOLS.

By LOUIS OTTOFY, D.D.S., Manila, P. I.

HAVING seen frequent reference to the subject of the examination of the teeth of children in the public schools, and of rendering dental services to them, it occurred to me that it might be of some aid to those who are interested in this work to publish what is being done along these lines in Manila, especially in view of the fact that the Hon. Secretary of the Interior laid particular stress on the point that he be furnished facts and statistics regarding similar work in other cities. I am of the opinion that more of this work has been done in Germany than anywhere else.

If the work is inaugurated here—as I believe it will be in a short time—its influence upon the future must be almost incalculable, viewed from any standpoint, whether the economic value of better constitutions in the coming race, the uplifting and elevating influences of cleanliness in these islands, the creation of a dental profession for the future by creating a demand for dentists, or from any other viewpoint.

In order to induce the department of Public Instruction to consider the matter, upon the request of the secretary thereof, I presented the following argument and facts:

"64 ESCOLTA, MANILA, Dec. 3, 1906.

"HON. W. MORGAN SHUSTER, Secretary of Public Instruction, Manila, P. I.

"Dear Sir,—In conformity with my

promise of some days ago, I have the honor of presenting for your consideration the subject of introducing free dental service for the needy poor in the public schools of Manila, and, also in accordance with my promise, to present statistics and facts bearing upon the subject.

"GENERAL CONSIDERATIONS.

"It is a known fact that dental caries existed in the remotest time of which there is any human record. No one can give a reasonably correct opinion as to the condition of the teeth of a people or race, no examinations of the teeth of adults of any community ever having been made except in such institutions as hospitals for the insane, asylums for the blind, deaf, dumb, etc. It would therefore be impossible to say with any claim to accuracy whether the teeth of the Filipinos are better or worse than the teeth of any other race, or whether there is any difference in the general average condition between Tagalog, Visayan, Negrito, Moro, etc.

"THE CONDITION OF CHILDREN'S TEETH.

"Examinations and tabulation of the condition of children's teeth have been made during the last twenty years in nearly every civilized country, and the records thus obtained form a scientific

and reliable basis for deduction. It is needless to go into extensive and interesting details of this subject at this time; suffice it to say that the first investigations of this character were made simultaneously by Parreidt⁽¹⁾ in Germany, and Ottofy⁽²⁾ in the United States, in 1882. Since then a great many similar investigations have been made and recorded, notably by Albinger in Austria, Ricer in Denmark, Cunningham and Pedley in England, Röse, Voerckel, Weber, Berten, Worm, Jessen, and Fenchel in Germany, Ungvár in Hungary, and Hyatt, Merrill, Fogg, Habbeger, Nesbit, Allen, Rivers, and others, in the United States. It is only fair to say that our German cousins have done more along these lines than men of any other nation.

"It is probably not necessary to go into the interesting details of results obtained; suffice it to say that the extent of caries ranges from 20 to 25 per cent. Four years ago, by permission of Mr. Atkinson, the then superintendent of education, I examined the teeth of 500 Filipino school children in Manila, and found the percentage to be 23.5. The examination covered 13,711 teeth. Of the 250 boys examined, only 13 had entirely sound teeth, while of the 250 girls, 11 enjoyed a like blessing. My carefully prepared tables reveal practically the same conditions as were found elsewhere. It is therefore not necessary to enter into a discussion of them; suffice it to say that the conditions are bad, and that there is much room for improvement, more so than anywhere else, for in other countries the examiners have found a number of filled cavities, while here in Manila in a total of 3777 only 3 had been filled. It would be superfluous under these circumstances to enter into any argument or present facts to show the urgent necessity of dental care.

"BENEFITS TO BE DERIVED.

"To the intelligent observer it seems also unnecessary to give reasons why the ravages of dental caries should be checked. In a general way there can be

no question on the point that a good condition of the masticatory organs cannot be otherwise than beneficial to the entire system. Where the teeth have been cared for, other improvements have been noted, such as the reduction of loss of time from studies, freedom from pain and consequent excuse for absence from school, improvement of eyesight, etc. In the Philippines there is also, in a large measure, the educational influence upon the children themselves and its reflection on the parents, thus preparing these people for higher and nobler things along a line hitherto practically closed to them.

"RESULTS ELSEWHERE.

"In the United States the profession is just waking up to the importance of this work, and in a number of places free dental services are rendered to the public school children, notably in Cleveland, Ohio; New York, N. Y.; Milton, Pa.; New Haven, Conn.; Boston, Mass., and other cities. It must also be remembered that there are about sixty dental colleges in the United States distributed in the larger cities, and that all of these have free clinics attached to them, and that they make efforts to reach the school children. My information from abroad is not as complete as might be desired; while I know of the establishment of free clinics in the public schools of many of the cities of Europe, I am unable at this moment to give the authorities except in regard to Paris, France, and Witten, Elberfeld, Mühlhausen, Darmstadt, Gleiwitz, Strasburg, and Hamburg, Germany. I find, however, from the periodical literature of the profession, that there is a wide awakening in this field. The profession realizing that progress toward the prevention of the enormous loss of teeth can best be made by closer attention to the growing generation. As an illustration I can cite, from the examination of the teeth of the Filipino children, the first permanent molar—sometimes referred to as the "sixth-year" molar. This tooth normally is supposed to appear at the age of six. My observations in the United States lead me to

believe that it appears in that country more nearly at five and one-half years; while here in the Philippines I have seen it *in situ* at five years, and earlier. It should also be borne in mind that this is the first tooth of the permanent set to make its appearance, and is considered, even by well-informed people, to belong to the temporary set of teeth, and hence not deserving of preservation. Of this class of tooth, in the 500 children referred to I examined a total of 1942, of which number 1184 were carious or lost before the age of fifteen.

"METHODS OF RELIEF.

"The free clinics are maintained and supported in various ways. In some, the municipality has furnished the funds, established the clinic, and supports it with the funds of the government; in others, dentists as individuals or associations have established and maintain the clinic from their own funds, or in part from municipal funds or donations of generous people; in other cases they are supported and established by bequest, while in still others these various forms intertwine.

"PLAN PROPOSED FOR MANILA.

"At the outset I desire to state most emphatically that under no circumstances do I ask for nor will I accept any compensation whatever, in any manner or form, for any service I may render in this cause; and that I will give as freely of my time as it is possible for a private citizen, depending solely upon his own energies for support, to give.

"In 1904, while on a trip to the United States, I secured, for any purpose which may promise the greatest benefit, dental appliances and materials to the value of \$800, from liberally disposed manufacturers and dealers in the United States who knew of my past labors for the profession. This material I deposited in St. Paul's Hospital, and organized a dental clinic, supplementing it with necessary instruments, appliances, books, etc., from my own supply. For one and a half

years I have quietly conducted that clinic, never asking or receiving any compensation therefor. To be sure I merely supervise the work, and try to do so without loss of my own time during the hours demanded by my practice. This is not always avoidable; the time thus devoted to it is taken principally from that which otherwise would be devoted to some form of recreation. I quote from the report of November 30, 1906, with the explanation that while the clinic was nominally established on May 1, 1905, by reason of the unfinished condition of the hospital it was not in full operation until about October 1 of that year, or fourteen months ago; and further, with the statement that the income was derived from such work as required an outlay, and was used for the purchase of material and for compensation of the native in charge of the clinic:

"Summary.

"Total number of patients, May 1, 1905, to November 30, 1906, inclusive	1006
"Total number of operations.....	3047
"Total cash receipts	\$P.472.56
"Total value of operations at usual fees prevailing in Manila.....	\$P.6189.00

"The service at Bilibid prison (Friday afternoons), inaugurated last June, is continued and highly appreciated. So far 201 patients have been treated there, and at present no one in the prison is in need of immediate attention. Arrangements have also been made to call the assistant (by phone) to the prison at any time his services may be needed.

"From the foregoing it may be seen that I have the appliances and material as well as an assistant to do the work. He is now free every afternoon except Friday.

"I make the following proposition:

"(1) That permission be granted to commence the work in some one of the schools, Tondo for instance. That services be rendered to the children absolutely free of cost either to them, the municipality, or the government, on a system and plan which I will devise so as to accomplish the most good with the least interference with the work of the

school, and with a view of popularizing the work. As the instruments and the assistant would have to be transferred daily to his work at the school, it is recommended that a conveyance (caromatta or carotella) be furnished for this purpose by the Bureau of Health or the school department (but even this is not insisted upon), for four afternoons per week, Monday to Thursday.

"(2) In course of time the benefit derived by the people will become a substantial demonstrable fact, and at the same time it will be impossible to expect the amount of service required of the assistant at his present rate of compensation. The service will then either have to be abandoned, or arrangements made to continue it on one of the following two plans: (a) The matter to be brought to the attention of wealthy natives, who will advance the funds to secure a portable equipment and a moderate addition to the compensation of the assistant; or (b) the municipality or the government render financial aid. I am of the opinion that \$P.500 will be ample for the equipment, and \$P.600 expended annually would cover the cost of material, extra compensation of assistant, and in fact all expenses, as the work for these children would consist in the removal of roots of carious teeth, simple fillings of amalgam, gutta-percha, and cement, cleaning, treatment of diseases of the gums, and such other attention which does not call for an outlay of much money.

"AUTHORITIES.

"In closing this appeal for dental services to the poor and the coming generation, I cannot do better than briefly quote from the writings of others anent this important work:

"Neither the municipal authorities nor even the state should be kept in ignorance of what might be done in a cause of such vital importance to the people."⁽¹⁾

"The idea of reaching (in a dental sense) the public in an educative way through the public schools, we regard as excellent."⁽²⁾

"There are two reasons why I urge the es-

tablishment of free dental service for the sick poor. In the first place, because the poor are sadly in need of such service. In the second place, because dental practitioners should, to a larger extent than is now common, give some fraction of their time in public work of a purely charitable nature."⁽³⁾

"If the mouths of children in public schools could be examined by competent dentists, carious or diseased teeth filled or extracted, and instructions given and enforced in regard to the intelligent use of brushes and antiseptics, the death-rate of this country would be materially lessened, the percentage of illness much reduced, and a stronger and more vigorous race result."⁽⁴⁾

"A movement is on foot for a tooth-brush campaign among New York city school children. . . . By dental attendance upon the children, there is no doubt that the health of the pupils would be much improved."⁽⁵⁾

"The South Carolina Dental Association offers to send lecturers to the public schools to instruct children how to care for their teeth."⁽⁶⁾

"Strasburg started the free care of children's teeth in 1902, and Darmstadt, Mühlhausen, and other cities followed suit. The third annual report from Strasburg states that there were 12,691 visits to the clinic last year, and that the children are improving in the care they give their teeth."⁽⁷⁾

"The Milton, Pa., dentists have taken a step in the right direction, and are taking care of the teeth of the school children whose parents are not in a position to pay for dental work. Working alternately, by agreement among themselves, and requesting no compensation, they give one day a month to this task."⁽⁸⁾

"It is inconceivable to some minds that men who are really competent will devote time to dental inspections which do not promise a money return, and as no fee is paid, they think there is clear proof of base motives for the undertaking—that such inspections are only means for the advertisement of the dentists. This suspicion only proves that those who make such statements are absolutely incapable of comprehending the importance of such researches."⁽⁹⁾

"The city will buy the material and equipment. The work will be furnished by the Cleveland Dental Association, and 1500 children, whose parents receive aid from the city, will be entitled to free treatment. The reasons given for the innovation are that the

digestion, and consequently the health of the children, will be improved by good teeth." (12)

" . . . The need (free dental service in the public schools of Brooklyn) is widespread, as is understood when one realizes that 55,300 school children were examined from March to December last year, and 18,000 were found to have defective teeth. The percentage of children needing dental care was doubtless greater, as the medical examiner fails to discover conditions that a dentist would see." (13)

"Dental inspection has been introduced in the schools of Gleiwitz, Germany, and is now engaging the attention of the authorities of Berlin." (14)

"It is evident that bad teeth influence the health of the children, and that the health of the entire people suffers by the propagation of caries, if energetic measures are not taken against this disease." (15)

"In the examination of the teeth of 3183 National school children, I found 86 children, or 2.7 per cent. who possessed an entirely sound set of teeth; these children were between six and fourteen years of age." (16)

"The school should put itself in the service of sanitation. Everything a child learns at school is impressed most strongly on its memory. . . . In the interest of dental hygiene, it would be of great utility to appoint school dentists, who from time to time would examine the teeth of the children, and if desired, treat them gratis." (17)

"A novel bequest was recently made to be used to pay for the proper care of the teeth of school children in a village in England, in cases where the parents could not meet the expense." (18)

"In the year 1896 there was established the Mellin Foundation in Hamburg, a dental institute appointed in the most sumptuous style. In what manner its existence as a permanent foundation has been fixed, and what arrangements exist for the maintenance of its effectiveness as a charitable institution, I have no authentic information." (19)

"It is clear that the colossal spread of dental caries in all strata of the population carries with it a great danger to public health, and this fact cannot be emphasized too often and too loudly. . . . The carious teeth form breeding-places for the bacilli, which again may become the starting-point of various diseases, and finally, the child may suffer great torture through resulting toothache. . . . The disturbance of digestion, with all its consequent symptoms, is by far the

most important and frequent injury which is brought about by dental caries. . . .

"During every act of drinking and eating, rotten, decomposed masses proceed from hollow teeth and putrefied roots and penetrate into the stomach. . . . In the same way as the school is the only place where by dental examination of the children a true picture can be obtained of the general decay of the human teeth, so the school is the only place which is really effectual for the introduction of dental hygiene to the people." (20)

"And so on, *ad libitum*, could I quote authority after authority. I think the above is sufficient precedent to enable you to arrive at a decision in the matter. Before proposing it to you I have endeavored to interest others of my *confrères* in the work, and while I have their promise of hearty co-operation, I know from previous experience that I have not much to expect until successful results are shown, when I shall receive all the assistance I need.

"Very respectfully,

"LOUIS OTTOFY."

The foregoing communication was acknowledged by the Hon. Secretary of Public Instruction, under date of December 22, 1906, as follows:

"With reference to your letter of December 3d, in which you present statistics and facts bearing upon the subject of introducing free dental service in the public schools of Manila, I have to inform you that the same was referred to the Director of Health and the Director of Education, who seem to take a favor-

able view of your proposition, but suggest that action be deferred until the arrival of a lady physician, who is expected here soon, as it is desired that she should have an opportunity first to make a medical report upon the schools."

The lady physician referred to is now (February 1907) making an examination of the school children, and I trust it will not be long before the work herein referred to is inaugurated.

OPSONISM APPLIED TO PYORRHEA ALVEOLARIS.

By G. S. JUNKERMAN, A.M., M.D., D.D.S., Cincinnati, Ohio.

THE multiplicity of remedies, the variegated aggregation of etiological opinions, and the continued chain of uninterrupted failures in the treatment of pyorrhea alveolaris, lead to but one conclusion—that dental surgery, backed by human intelligence, has not yet triumphed in the therapy of this not uncommon disease. Inspired by an article in the March number of the *International Journal of Therapy* and written by Dr. Otto Juettner, on the subject of "The Opsonic Question," I have presumed to think that a light has at last broken on our way, pointing to a natural explanation of the disease; and this in turn may lead to a curative therapy for it. This author's concise explanation of the "opsonic question" will be my apology for quoting freely from his article.

Fine-spun theories as to whether this disease be constitutional or local avail nothing unless we find that constitutional treatment is curative of it; since the only manifestation we have of it is a local one. When the teeth are gone the disease is gone. This is almost convincing evidence that local therapy will be the effective treatment. If a man have rheumatism in his toe, removal of the toe will not cure the disease except so far as the toe itself is concerned. It will appear somewhere else, because

rheumatism is a constitutional disease. Those who advocate the constitutionality of pyorrhea alveolaris have for their contention but a single leg on which it can stand, and that is the unavailability of local treatment.

To place the subject squarely before you in conjunction with the opsonic question, let us start with the hypothesis that pyorrhea alveolaris is a local infectious disease, being consequently of bacterial origin, the bacteria having been absorbed by the peridental membrane or selected by it from bacteria which have been taken into the blood in a constitutional way. The selective power of the peridental membrane for this particular kind of bacteria would be the only way that the disease could arise from the general circulation. This becomes the more positive in the absence of any constitutional symptoms, which so far have not been discovered. It is quite possible, also, that this particular kind of bacteria might upon examination be discovered in the general circulation, having been absorbed by the peridental membrane externally and being harmless to the other tissues of the body. The most rational conclusion, based upon the hypothesis assumed and fortified by the brief known etiology of the disease, is that if the disease be of a bacterial

origin, the bacteria are absorbed from without. This conclusion is doubly fortified and the selective theory of the peridental membrane is exploded from the fact of there being other membranes in the body similar to the peridental membrane which are never infected with this disease. Furthermore, these theories cannot be controverted, even if, when the correct therapy be discovered, our remedy shall be found to be most effectively administered constitutionally. Pyorrhea alveolaris is characterized by death of the peridental membrane through pus formation around it, and pus formation requires bacteria. The opsonic question has to do with the destruction of bacteria as antagonizing disease and its destructive tendency.

To quote from the author above referred to, "The pioneer work in this important department of biology was done by Metchnikoff, who studied the rôle which the white corpuscles of the blood play in the protection of the animal body against germs of disease and their destructive activity. Metchnikoff showed that the white corpuscles in reality are protectors and defenders of the body, inasmuch as they actually wage war against the intruding germs of disease, attacking and destroying them. He called them phagocytes (eating-cells), because they devour the invading bacteria. The process itself he called phagocytosis. This subject was taken up, studied, and elaborated by many observers, who elicited many new and interesting details. It was found that the fighting quality or eating capacity of the blood-cells is variable, and dependent upon many circumstances. The so-called phagocytes do not at all times possess the same degree of power to cope with pathogenic intruders. Sometimes their power is very slight; under other circumstances it is very considerable. If this power be so great that germs of disease can enter the body without being able to do harm, the body, as the result, is practically proof against their activity; this condition is called *immunity*. It represents the highest phagocytic power of the blood cells."

Under this condition it is quite possible that the bacteria producing pyorrhea alveolaris may be present in the mouth and yet no infection take place, because of the high opsonic index of the individual—or of the membrane, if the disease be entirely a local one. This would constitute a condition of immunity.

To quote further, Leishman, Wright, Douglass, Bulloch, and others studied the subject of phagocytosis from many points of view. It was elicited that the fluids of the blood themselves possess certain properties that affect the phagocytic action of the blood-cells. Wright used for his earliest experiments the cultures of one of the pus-producing germs, the staphylococcus pyogenes aureus. He attributed the peculiar effects observed to the action of certain elements contained in the blood fluids. These elements modify the bacteria, weaken them, and in this way render them a ready prey to the phagocytes. Since the bacteria are devoured by the phagocytes, the action of the elements in the blood fluids is similar to the function of the cook who prepares the food for eating. In this case the bacteria are the food. The cook is represented by the elements in the blood fluids which modify the bacteria, or render the food eatable. These elements in the blood fluids were for this reason called *opsones* or *opsonins*. The Greek word ὀψων means a "side dish." The verb ὀψωνέω means "to provide food" or "to prepare food." Thus the meaning of the word "opsonin" becomes plain.

Ross, in a splendid monograph on the subject, summarized the matter as follows:

"(1) Opsonins act by chemically uniting with the invading bacteria, and so altering them that leucocytes are able to *phagocyte* the bacteria and destroy them. It is important to remember that these substances do not stimulate or otherwise affect the leucocytes.

"(2) It is probable that there are present many varieties of opsonins in the blood plasma, each having to do with combating a particular kind of microbic invasion.

"(3) Opsonins have been shown to be distinct from other bacteriotropic substances, such as bacteriolysins, the agglutinins, and antitoxins."

The comparative estimation of a patient's power of resistance to an invasion of a given germ is called the "opsonic index" of the patient. To find the opsonic index of a patient for any given microbe, the serum to be tested is mixed with fresh human leucocytes and the mixture observed in its action upon the particular bacterium under investigation. This opsonic index assumes practical importance because it seems to bear a definite relation to an individual's resistance against a given disease-producing microbe. With subacute and chronic infections the opsonic index is usually low for the corresponding bacterial species.

Wright has shown that by artificial bacterial auto-inoculation one may increase resistance against the corresponding organism to a point at which the healing of infectious processes occurs. The bare fact that immunity could be induced or heightened by the use of pathogenic bacteria or their products had been established and extended from the day of Pasteur's epoch-making studies in the bacteriology of infectious diseases; and from Buchner's day it was shown that the blood serum bore an important part in the body's combat against micro-parasites; while the rôle of the living body-cell was demonstrated by the brilliant Metchnikoff. But figuratively it remained for Wright to so modify the vaccine of Pasteur as to arouse in the serum of Buchner a substance which prepared the disease-producing microbe for destruction by the phagocyte of Metchnikoff; thus bringing to practical humanitarian usefulness the laboriously studied theories of three pioneers in biologic therapy. (Ohlmacher.)

The chief and only object in the treatment is to *raise the opsonic index*.

Wright's method is limited to bacterial infections, and is most favorable in those cases having a low opsonic index. For the sake of illustrating the plan, let us assume that we have to treat a case of pustular acne: The first thing to do is to

examine the pus to determine the organism present. Next find the patient's opsonic index. If it be low, vaccine inoculations should be made. A vaccine as it is understood here is a standardized, sterile emulsion of the organisms found in the pus of the lesion. Under aseptic precaution inject into the patient a vaccine of two hundred and fifty million cocci. When this is done it becomes very interesting to observe what now takes place in the patient. Immediately following the injection there is a fall of the opsonic index, but a reaction soon takes place and the index begins to rise, and within from four to six days the index will reach the normal and will go above it, remaining stationary for a few days, when it will begin to fall again. The curve will graphically represent the exact conditions. The falling index is called the "negative phase," the increasing index is called the "positive phase," and the stationary condition is called "high tide." The patient's blood is kept under examination, and when the second "negative phase" appears and the index is returning to normal, another inoculation with vaccine should be made. The index continues to fall after the second injection is given, but reaction soon follows, and the index shoots up again, and probably higher than before, remains stationary, then begins to fall. In such cases an inoculation should be made about every ten days, but in all cases they should be controlled entirely by the index. After a few inoculations, as a rule, marked improvement will be observed in the patient.

The preceding statements are quoted from a summary of the subject by J. M. King of Nashville.

Wright's fundamental rules for therapeutic applications in cases of bacterial infections are—

- (1) Isolate in pure culture the causative micro-organisms.
- (2) Estimate the opsonic power of the patient's blood to this micro-organism.
- (3) If the opsonic index be at or below normal, prepare and standardize a vaccine from this micro-organism.

(4) Inoculate the patient with this vaccine with appropriate doses and at proper intervals, as shown by a systematic estimation of the opsonic content of the patient's blood.

What the influence of Wright's attractive and ingenious theory will be on the therapy of bacterial diseases, it is as yet too early to tell. In the light of his researches the *vis medicatrix naturæ* ceases to be a theoretical abstraction or a convenient generalization. It becomes a physical entity accessible alike to the chemist, the pathologist, and the bacteriologist. Strangely enough, the brilliant work of two such master-minds as Metchnikoff and Wright bears out the truth of a statement of a humble layman, who more than sixty years ago said that all contagious diseases contain in their contagion the materials necessary for their cure. That humble layman was Vincenz

Priessnitz, the crude father of modern hydrotherapy.

From these suggestions it is but a step to associate pyorrhea alveolaris with a condition where the low opsonic index prevails in the peridental membrane. If such be the case the cure would be elevation of the index. Can that be done with drugs? It has been repeatedly tried without success, except of a temporary nature. Could a vaccine serum be made from the products of the disease itself and injected, so as to raise the opsonic index? It is well worth the trial, since all else has so dismally failed.

The opsonic question being one of such recent birth, its possibilities cannot yet be determined; but we believe that, if the discoveries so far made are correct and are applicable to the disease, we will find it a wonderful aid in the treatment, and possibly the long-looked-for cure, of pyorrhea alveolaris.

PHARMACOPEIAL REVISION.

By EDWARD HOFFMEISTER, A.B., D.D.S., Baltimore, Md.

(Read at the union meeting of the Maryland State Dental Association and the District of Columbia Dental Society, Washington, D. C., June 7, 1906.)

THE need to compile and formulate a National Pharmacopeia must have been apparent long before 1820, in which year the first United States Pharmacopeia, projected and fostered by Dr. Lyman Spalding of New York city, made its appearance. The necessity of standardizing drugs and their preparations, and the reliance to be placed upon such systematized manuals is evidenced in that prior to this time the various European pharmacopeias were depended upon by the physicians and pharmacists of this country.

A common misconception of the scope of the Pharmacopeia consists in the belief that an official drug, i.e. one receiving pharmacopeial recognition, must

necessarily be therapeutically efficient. Efforts have been made to include those drugs only whose accredited virtue is accepted and utilized by the great majority of practitioners, but it has been deemed wise to retain the representative character of the work.

The idea that framers of a pharmacopeia keep in mind is not to determine the value or inertness of a drug, but to see that the prescribed or purchased article is dispensed pure and that uniform preparations of the same may be obtained.

Dr. H. C. Wood, president of the United States Pharmacopeial Convention, explains the *motif* of a pharmacopeia thus: "If five thousand doctors in

the United States believed brickdust to be a valuable remedy and habitually used it, brickdust would have to go into the Pharmacopeia. Witch-hazel is probably as active and as useful as is brickdust, but witch-hazel is a fad and is enormously called for, and so witch-hazel must go into the Pharmacopeia. The Pharmacopeia exists for the purpose of requiring the apothecary to give, in the first place, pure brickdust or pure witch-hazel when asked for; and in the second place, uniform preparations of these remedies."
